Countervailing Power*

Simon Loertscher† Leslie M. Marx‡

May 31, 2020

Abstract

Merger defenses based on countervailing power stipulate that mergers on one side of the market increase social surplus by offsetting power on the other. Despite its popular appeal, countervailing power has proven controversial and difficult to formalize. We provide an incomplete information bargaining model in which horizontal mergers can increase social surplus by equalizing bargaining weights. Moreover, horizontal mergers can harm rivals; a presumption that vertical integration is socially beneficial has no basis; bargaining breakdown occurs on the equilibrium path; and non-contractible investments are efficient if and only if bargaining is efficient. The model naturally gives rise to bargaining externalities.

Keywords: price formation, bargaining power, productive power, vertical integration, investment incentives

1 Introduction

Countervailing power features prominently in antitrust debates. The idea that increasing market power on one side of the market countervails existing market power on the other side is appealing to many and at times embraced as if it had “talismanic power” [Steptoe 1993]. Nonetheless, the concept of countervailing power has been controversial since its inception, with John Galbraith viewing it as a mitigant of economic power of “substantial, and perhaps central, importance” and George Stigler lamenting the lack of any explanation for “why bilateral oligopoly should in general eliminate, and not merely redistribute, monopoly gains.” A considerable part of the controversy arises because formalizing countervailing power has proved challenging. As George Stigler’s comment makes clear, it requires a model in which bargaining power affects not only the division but also the size of social surplus. This is challenging because, as noted by the New Palgrave Dictionary, “it is difficult to model bilateral monopoly or oligopoly, and there exists no single canonical model.”

In this paper, we provide a model that has precisely these properties. We consider a procurement problem with one buyer and one or more suppliers in which private information pertains to both sides of the market. We assume that the buyer’s value and the suppliers’ costs are independent draws from continuous distributions with compact supports. The distributions are common knowledge, but the realized value and costs are the buyer’s and the suppliers’ private information. Bargaining is modeled as an incentive-compatible, individually-rational price-formation mechanism that maximizes the weighted sum of expected buyer and supplier surplus, subject to a no-deficit constraint, with the weights in the objective reflecting the relative bargaining powers of the buyer and the suppliers, which is why we refer to them as the agents’ bargaining weights. In general, the bargaining weights affect both the division and the size of expected social surplus. The outcomes of incomplete information bargaining coincide with the set of Pareto undominated second-best outcomes.

The main insights from this paper are the following. A horizontal merger that “levels the playing field” by equalizing bargaining weights can improve social surplus. Indeed, it can make the first-best possible when, prior to the merger and the change in bargaining weights, the first-best was not achievable because the price-formation process was too strongly tilted towards the buyer. In contrast, a horizontal merger between suppliers that does not affect the bargaining weights never improves social surplus and always makes achieving the first-

---

1 Galbraith (1954, p. 1) and Stigler (1954, p. 13), respectively.
2 Snyder (2008, p. 1188). As Carlton and Israel (2011, p. 128) put it: “For changes in bargaining outcomes due to a buyer merger to create a true efficiency, it must be that, post-merger, the parties are better able to arrive at an optimal nonlinear price schedule, perhaps due to lower transactions costs, which moves output closer to the competitive level.”
best more difficult because the merger eliminates a bid and thereby exacerbates the deficit problem of the price-formation process.

To understand how countervailing power is obtained, it is useful to distinguish between an agent’s productive power (or strength) and its bargaining power. Productively stronger buyers have, or tend to have, higher values, and productively stronger suppliers have, or tend to have, lower costs. In contrast, an agent’s bargaining power captures its ability to affect the price-formation process in its favor. While, empirically, productive power and bargaining power may be correlated, conceptually, they are distinct and independent. As a case in point, both business and leisure air travellers are price-takers and hence have the same amount of bargaining power, that is, none. However, business passengers are productively stronger, which is why they are charged higher prices. A merger between two suppliers creates a productively stronger supplier that draws its cost from the minimum of the two pre-merger distributions, without per se increasing the bargaining power of the new firm. Changes in bargaining power are necessary, without being sufficient, for there to be countervailing power because, keeping bargaining weights fixed, the bid elimination associated with a merger always makes the deficit problem for the price-formation process more severe. Countervailing power therefore requires there to be unequal bargaining weights before the merger and more equal bargaining weights post merger. Consequently, a merger defense based on countervailing power arguments needs to demonstrate that the buyer has greater bargaining power pre merger—evidence for which will depend on the price-formation process in a given industry; for example, in a procurement auction, it includes discriminatory reserve prices, discounts and handicaps in the auction, and random winner selection—and provide a theory for why this power diminishes without vanishing through the merger.

We show that vertical integration between the buyer and a supplier can create a bilateral trade problem à la Myerson and Satterthwaite (1983) in which the first-best becomes impossible when it was possible prior to integration. This occurs, for example, when vertical integration leaves only one independent supplier in the market and when the buyer’s lowest possible value before integration exceeds the suppliers’ highest possible cost. In situations like these, vertical integration is thus socially harmful. It is so in ways and for reasons that are absent when the efficiency of the price-formation process is exogenously fixed. Of course, vertical integration also eliminates a bilateral trade problem, namely that within the newly created entity. Therefore, the social surplus effects of vertical integration can go either way. Importantly, we show that under appropriate assumptions, the likely effects of vertical integration can be estimated using pre-integration data, including the frequency of bargaining breakdown. Although our analysis does not imply that vertical integration is universally bad, it does show that a presumption that vertical integration improves social surplus is not
warranted.

These results are obtained in the most basic economic model of exchange with a one-off transaction between a buyer and suppliers. But, of course, the incomplete information bargaining approach can also be embedded in a dynamic setting in which agents first make non-contractible investments and bargain once their values and costs are realized. This extension is in part motivated by the upsurge of interest in investment incentives following the Dow-DuPont merger decision and in part because of the prominence of both bargaining weights and non-contractible investments in the theory of firm à la Grossman-Hart-Moore. As does this literature, we assume that investments are not contractible, which implies that the price-formation process does not vary with investments off the equilibrium path, and we assume that investments improve distributions in the sense of first-order stochastic dominance shifts without affecting the supports. In this setup, the equilibrium investments are efficient if and only if bargaining is efficient. The contrast to the results obtained in the theory of the firm could hardly be sharper. There, complete information and efficient price formation (for example, Nash bargaining or Shapley value) are imposed by assumption and induce hold up and thereby inefficient investments. The privacy of information in incomplete information models protects agents against hold up. Beyond highlighting another fundamental difference relative to complete information models, this analysis allows us to connect vertical integration, which affects whether incomplete information bargaining is efficient, with the efficiency of investment.

The incomplete information bargaining approach is also amenable to introducing variations in agents’ outside options, which occupy center stage in complete information bargaining. In the incomplete information setting, outside options can affect an agent’s cost of participating in the mechanism independently of whether the agent trades and can affect its value or cost distribution by shifting its support. The comparative statics with respect to increasing an agent’s participation cost are intuitive and largely the same as in models with complete information because it increases the agent’s share of the surplus that is created; in contrast to complete information models, it may decrease expected social surplus. The effects of changing an agent’s production-relevant outside option are more nuanced. For example, as a supplier’s outside option improves, the support of its cost distribution shifts.

---

4As we discuss, a similar result holds for investment by the suppliers in quality.

5Of course, to the extent that outside options affect bargaining weights, the comparative statics are those discussed above.
upwards, meaning that higher costs become more likely. Hence, the supplier will tend to be less likely to trade. However, under the assumption of monotone hazard rates, this effect is partly (but not completely) offset by the fact that, for a given cost realization, its weighted virtual cost is lower than before the increase in the outside option. This implies that, ex post, given the same cost realization, the supplier is treated more favorably after the outside option increased, which is in line with intuition gleaned from complete information models. However, from an ex ante perspective, the increase in the outside option harms the agent because overall it makes it less likely to trade and thereby decreasing its ex ante expected payoff. Moreover, as its distribution worsens, the revenue constraint faced by the mechanism becomes tighter, which further tends to harm the agent.

By allowing for multi-object demand and supplier-specific preferences by the buyer, the model also naturally gives rise to bargaining externalities. We provide conditions under which an increase in the buyer’s preference for one supplier’s product increases the payoffs for all of the suppliers. This occurs when an increase in a buyer’s preference for a supplier improves the efficiency of incomplete information bargaining to the benefit of all suppliers.

The remainder of the paper is structured as follows. Section 2 introduces the setup. In Section 3 we derive the price-formation process that incorporates bargaining weights and provides a model of incomplete information bargaining. We also derive the relationship to the Pareto frontier, provide an illustration, and discuss implementation. Results pertaining to horizontal and vertical mergers are in derived in Section 4. Section 5 extends the model to allow investment, variation in outside options and opportunity costs for the agents, and multi-object demand with supplier-specific preferences. In Section 6 we discuss related literature. Section 7 concludes the paper. The formal mechanism design results and longer proofs are relegated to appendices. An axiomatic approach to incomplete information bargaining is contained in the online appendix.

2 Setup

We consider a procurement setup with \( n \) suppliers indexed by \( i \in N \equiv \{1, \ldots, n\} \), each with the capacity to produce one unit of a good, and one buyer, labeled \( B \), with demand for one unit of the good.

The buyer draws its value \( v \) independently from a distribution \( F(v) \) with support \( [\underline{v}, \overline{v}] \) and density \( f(v) \) that is positive for all \( v \in (\underline{v}, \overline{v}) \). Supplier \( i \) draws its cost \( c_i \) independently from distribution \( G_i(c_i) \) with support \( [\underline{c}, \overline{c}] \) and density \( g_i(c_i) \) that is positive for all \( c_i \in (\underline{c}, \overline{c}) \). We assume that \( F \) and \( G_1, \ldots, G_n \) are common knowledge, while the realized value \( v \) and the realized costs \( c_1, \ldots, c_n \) are the private information of the buyer and individual suppliers,
respectively. To save on notation, we ignore ties among the agents’ types. Consistent with
the literature, we model a merger between two suppliers as creating a merged entity whose
cost is drawn from the distribution of the minimum of two independent cost draws, one
from each of the two merging suppliers’ distributions. That is, a merged entity formed from
suppliers $i$ and $j$ draws its cost $c$ from the distribution
$$
\hat{G}(c) \equiv 1 - (1 - G_i(c))(1 - G_j(c)).
$$
(1)

The buyer and the suppliers have quasilinear preferences. The expected payoff of supplier
$i$ with cost $c_i$ when producing the good with probability $q_i$ and receiving the expected
monetary transfer $m$ is
$$
\hat{u}_i(c_i; m, q_i) = m - c_i q_i.
$$
(2)
The expected payoff of a buyer with value $v$ when receiving the object with probability $q$
and making the expected monetary payment $m$ is
$$
\hat{u}_B(v; m, q) = vq - m.
$$
(3)

Under ex post efficiency (and ignoring ties), trade occurs between the buyer and supplier
$i$ if and only if $v - c_i > \max_{j \neq i} \{0, v - c_j\}$. The problem is trivial if $\bar{v} \leq \underline{c}$ because then it is
never ex post efficient to have trade with any supplier. Therefore, we assume that $\bar{v} > \underline{c}$.

Because we allow both the buyer’s value and the suppliers’ costs to be random variables
whose realizations are the agents’ private information, the setup is symmetric with respect to
the privacy of information, with the important consequence that ex post efficiency need not
be possible. Indeed, for $n = 1$, our setup encompasses the classic Myerson-Satterthwaite
(1983) setting, where, as they show, ex post efficient trade is impossible if and only if $v < \bar{c}$.
We refer to the case with $v < \bar{c}$ as the case with overlapping supports and the case with $v \geq \bar{c}$
as the case of nonoverlapping supports. With one supplier and nonoverlapping supports, we
obtain ex post efficient trade even under incomplete information, but differences with a
complete information setup remain.

We denote the buyer’s virtual value function by $\Phi(v) \equiv v - \frac{1 - F(v)}{f(v)}$ and supplier $i$’s virtual

---

6 To avoid informed-principal problems, we model the mechanism-design problem as one in which a third
party without private information—such as a broker or “the market”—organizes the exchange. Although our
setup has properties that are sufficient for the informed-principal problem to have no material consequences
(see Mylovanov and Tröger 2014), it seems wise to circumvent the associated technicalities. Of course, by
giving all the bargaining power to the buyer, we still obtain the buyer-optimal mechanism, just as one would
if we assumed that the buyer organizes the exchange.

7 For example, the predictions of the models are starkly different when trade is preceded by noncontractible investments, as in the extension of Section 5.1 because the privacy of information in our setting provides protection against hold-up.
cost function by $\Gamma_i(c) \equiv c + \frac{G_i(c)}{g_i(c)}$\footnote{If $f(v) = 0$, then define $\Phi(v) \equiv \lim_{v \uparrow v^*} \Phi(v)$, and if $g_i(c) = 0$, then define $\Gamma_i(c) \equiv \lim_{c \downarrow c^*} \Gamma_i(c)$. If $f(v) = 0$, then $\Phi(v) = -\infty$, and if $g_i(c) = 0$, then $\Gamma_i(c) = \infty$.} We assume that the virtual value and virtual cost functions are increasing\footnote{The assumption of increasing virtual type functions can be relaxed through the use of “ironing.”} For $a \in [0, 1]$, we define the $a$-weighted virtual value function by $\Phi_a(v) \equiv v - (1 - a)\frac{1 - F(v)}{f(v)}$ and the $a$-weighted virtual cost function for supplier $i$ by $\Gamma_{i,a}(c) \equiv c + (1 - a)\frac{G_i(c)}{g_i(c)}$.\footnote{This departs from standard notation in that the coefficient on the hazard rate term is $1 - a$ rather than $a$, but because we will be introducing bargaining weights, this modification is useful.} Observe that monotonicity of $\Phi(v)$ and $\Gamma_i(c)$ implies that $\Phi_v$ and $\Gamma_{i,a}(c)$ are also monotone. As observed by Mussa and Rosen (1978), $\Phi(v)$ can be interpreted as a marginal revenue function. Analogously, $\Gamma_i(c)$ has the interpretation of being supplier $i$’s marginal cost function.

Although we focus on a procurement setting with one buyer and one or more suppliers, all of our results extend with the appropriate adjustments to a sales auction with one supplier and one or more buyers. In addition, as we show in Section 5.3 the setup can be extended to allow for multi-unit demand and supplier-specific preferences.

3 Incomplete information bargaining

At the heart of essentially any economic model of exchange are assumptions that govern the price-formation process. For example, oligopoly models specify a mapping from firms’ actions to prices, and models based on Nash bargaining specify a mapping from preferences to trades and transfer payments. As mentioned in the introduction, we stay within this tradition by working with a given price-formation process, but we add to it by introducing a price-formation process that allows for heterogeneous bargaining weights and that has neither the shortcoming of standard oligopoly models that buyers are price takers nor the problem of Nash bargaining that outcomes are efficient by assumption\footnote{For evaluating the merits of a countervailing power argument, the standard oligopoly models of Cournot and Bertrand are “dead on arrival” because one side of the market—typically, buyers—is characterized by price-taking behavior and hence has no bargaining or market power. The assumption of efficiency embedded in generalized Nash bargaining preempts any social surplus increasing effects of changes in the bargaining weights because the outcome is efficient both before and after the change. As noted by Ausubel et al. (2002, p. 1934), the results of Myerson and Satterthwaite (1983) imply that the search for efficiency is “fruitless.” Indeed, any axiomatic bargaining approach that stipulates efficient bargaining rules out transaction costs by assumption. In light of the Coase Theorem, which put the question of transaction costs on center stage in economics, this limits the value of the approach.}. 

\[\text{cost function by } \Gamma_i(c) \equiv c + \frac{G_i(c)}{g_i(c)}\]
3.1 Price-formation mechanism

We model the price-formation process as a mechanism that maps agents’ types into prices and probabilities of trading. Specifically, we assume that the price-formation process is a direct mechanism \( \langle Q, M \rangle \) that maps the buyer’s and suppliers’ types to quantities (or probabilities of trade) for the buyer and suppliers, \( Q : [v, \overline{v}] \times [c, \overline{c}]^n \rightarrow [0, 1]^{n+1} \), where feasibility requires.

\[
Q_B(v, c) \leq \min \{1, \sum_{i \in \mathcal{N}} Q_i(v, c)\}, \quad (4)
\]

and transfers for the buyer and suppliers, \( M : [v, \overline{v}] \times [c, \overline{c}]^n \rightarrow \mathbb{R}^{n+1} \). (Of course, excess production will never be optimal, implying that \( \sum_{i \in \mathcal{N}} Q_i(v, c) \leq 1 \) and \( (4) \) will hold with equality.)

This price-formation mechanism is required to satisfy incentive compatibility, individual rationality, and no deficit. A direct mechanism is incentive compatible if it is in the best interest of every agent to report its type truthfully to the mechanism and is individually rational if each agent, for every possible type, is weakly better off participating in the mechanism than walking away, where we normalize the payoffs of not trading and of walking away—that is, the value of the outside option—to zero. A direct mechanism has no deficit if the expected payment from the buyer is greater than or equal to the sum of the expected payments to the suppliers. For formal definitions, see Appendix A.1.

Fix a mechanism \( \langle Q, M \rangle \) and type realizations \((v, c)\). Then for an allocation rule \( Q \) with \( Q_i(v, c) \in \{0, 1\} \) for all \( i \in \{B \cup \mathcal{N}\} \), the buyer’s ex post surplus as a function of the type realizations is

\[
U_{B,Q,M}(v, c) \equiv \hat{u}_B(v; M_B(v, c), Q_B(v, c)) = vQ_B(v, c) - M_B(v, c),
\]

where \( \hat{u}_B \) is the function introduced in \( (3) \). Similarly, the ex post surplus of supplier \( i \) is given by

\[
U_{i,Q,M}(v, c) \equiv \hat{u}_i(c_i; M_i(v, c), Q_i(v, c)) = M_i(v, c) - c_iQ_i(v, c),
\]

where \( \hat{u}_i \) is the function introduced in \( (2) \). The budget surplus generated by the mechanism

\[^{12}\text{Other than being explicit about the nature of the price-formation process, there is nothing special to this approach because any equilibrium allocation has these properties, regardless of whether the model has complete or incomplete information. However, for complete information models, the dependence on agents' types is often degenerate insofar as each agent has only one (known) type.}\]

\[^{13}\text{In our independent private values setting, any Bayesian incentive compatible and interim individually rational mechanism can be implemented with dominant strategies and ex post individual rationality. By construction, it yields the same interim and hence ex ante expected payoffs and revenue. Thus, while we formally state our assumptions in Appendix A.1 in terms of Bayesian incentive compatibility and interim individual rationality, one could also use the ex post versions of those constraints.}\]
is
\[
R_M(v, c) \equiv M_B(v, c) - \sum_{i \in N} M_i(v, c),
\]
and the welfare or social surplus generated by the mechanism is
\[
W_Q(v, c) \equiv \sum_{i \in N} (v - c_i)Q_i(v, c).
\]

To capture bargaining power, we endow the agents with bargaining weights
\[
w = (w_B, w_1, \ldots, w_n),
\]
where \(w_B \in [0, 1]\) is the buyer’s bargaining weight and \(w_i \in [0, 1]\) is supplier \(i\)’s bargaining weight. We assume that at least one agent’s bargaining weight is positive. We define weighted welfare with bargaining weights \(w\) to be
\[
W_{Q,M}^w(v, c) \equiv w_BU_{B,Q,M}(v, c) + \sum_{i \in N} w_iU_{i,Q,M}(v, c).
\]

We evaluate market outcomes in the usual way according to the expected value of welfare, \(\mathbb{E}_{v,c}[W_Q(v, c)]\).

A mechanism is a first-best mechanism if it maximizes \(\mathbb{E}_{v,c}[W_Q(v, c)]\) subject to incentive compatibility and individual rationality, and it is a second-best mechanism if it maximizes that objective with the additional constraint of no deficit, \(\mathbb{E}_{v,c}[R_M(v, c)] \geq 0\). The first-best and second-best quantities or outcomes are then the quantities or outcomes that arise in the first-best and second-best mechanisms, respectively.

We use incomplete information bargaining with bargaining weights \(w\) to mean the price-formation mechanism that maximizes expected weighted welfare, \(\mathbb{E}_{v,c}[W_{Q,M}^w(v, c)]\), subject to incentive compatibility, individual rationality, and no deficit. Notice that, because we evaluate outcomes according to expected welfare \(\mathbb{E}_{v,c}[W_Q(v, c)]\), the bargaining weights \(w\) are indeed only bargaining weights, that is, they do not affect how outcomes are evaluated, although they affect the distribution of social surplus and, as we will see, sometimes the size of social surplus. Bargaining weights of \(w = (1, 0)\), for example, imply that the buyer has all the bargaining power, while bargaining weights \(w = (0, 1)\) imply that the suppliers have all the bargaining power.\(^{14}\)

---

\(^{14}\)Because there are multiple suppliers, the notion of suppliers having all the bargaining deserves brief elaboration. It means that the mechanism produces the same outcome as one in which a single supplier with cost equal to the minimum of the costs of all the suppliers makes a take-it-or-leave-it offer to the buyer.
The Lagrangian associated with the problem of

\[
\max_{(Q,M)} \mathbb{E}_{v,c} \left[ W^w_{Q,M}(v,c) \right] \quad \text{s.t.} \quad \mathbb{E}_{v,c} \left[ R_M(v,c) \right] \geq 0
\]  

(5)

can be written as

\[
\max_{(Q,M)} \mathbb{E}_{v,c} \left[ W^w_{Q,M}(v,c) + \rho R_M(v,c) \right],
\]

where \( \rho \) is the Lagrange multiplier associated with the no-deficit constraint. Using the mechanism design techniques described in Appendix A.1, we can use incentive compatibility to write this as an expression that has one term involving fixed payments to the worst-off types and another term given by

\[
\mathbb{E}_{v,c} \left[ \sum_{i \in N} \left( w_B \left( v - \Phi(v) \right) + w_i \left( \Gamma_i(c_i) - c_i \right) + \rho \left( \Phi(v) - \Gamma_i(c_i) \right) \right) Q_i(v,c) \right].
\]

(6)

Because any budget surplus can be reallocated to the agents through fixed payments, the shadow price of budget surplus, \( \rho \), satisfies \( \rho \geq \max w \). In addition, because a positive expected budget surplus is always possible given our assumption that \( \bar{v} > \underline{c} \), the shadow price is finite. Denoting by \( Q_\rho \) the pointwise maximizer of (6) for a given \( \rho \), the optimum is characterized by the smallest \( \rho \) greater than or equal to \( \max w \) such that the no-deficit constraint is satisfied at \( Q_\rho \).\footnote{This follows by the same arguments that were first developed in the working paper version of Gresik and Satterthwaite (1989) and that were first used in published form in Myerson and Satterthwaite (1983).} It is convenient to work with the inverse of the multiplier, \( \beta = 1/\rho \), which is an element of \( (0, \frac{1}{\max w}] \). We denote the largest \( \beta \in (0, \frac{1}{\max w}] \) such that the no-deficit condition is satisfied by \( \beta^w \), which we refer to as the budget parameter.\footnote{While we do not pursue it here, our approach generalizes directly to the requirement that the mechanism needs to generate a budget surplus of \( K \in \mathbb{R} \), which is not more than the maximum budget surplus that any incentive-compatible, individually-rational mechanism can generate. The second-best mechanism that generates \( K \), but otherwise maximizes the same objective, has an allocation rule as defined in Lemma \( \ref{lemma:second_best} \) but with \( \beta^w \) replaced by \( \beta^K \), which is a decreasing function of \( K \). Interpreted in this way, we have \( \beta^w = \beta^K(w) \).}

An immediate implication of this definition is that when \( w = 1 \), indeed whenever bargaining weights are symmetric, the incomplete information bargaining delivers the second-best quantities. As an illustration, consider a bilateral trade problem, i.e., assume \( n = 1 \). As mentioned, efficient trade is impossible if and only if the supports overlap, i.e., \( \underline{v} < \bar{c} \). Because bargaining weights of \( w = (1,1) \) yield the second-best outcome, this implies that \( \beta^{(1,1)} < 1 \) holds if and only if the supports overlap. With nonoverlapping supports, i.e., \( \underline{v} \geq \bar{c} \), the incentive-compatibility and individual-rationality constraints can be satisfied by charging the buyer \( v \) and paying the supplier \( \bar{c} \), generating a surplus of \( v - \bar{c} \geq 0 \), which can then be shared between the buyer and the supplier. More generally, for \( w = (1,0) \), we obtain the
buyer’s optimal mechanism. Because the buyer is essentially the residual claimant and so
prefers not to trade rather than accepting a deficit, this mechanism does not run a deficit,
implying that $\beta^{(1,0)} = 1$. Similarly, for $\mathbf{w} = (0, 1)$, we have the suppliers’ optimal mechanism,
which for analogous reasons does not run a deficit either, implying that $\beta^{(0,1)} = 1$.

Ignoring ties, which occur with probability zero, the allocation rule for incomplete infor-
mation bargaining is given in the following lemma:

**Lemma 1.** The allocation rule of incomplete information bargaining with bargaining weights $\mathbf{w}$, $Q^w$, has, for $i \in \mathcal{N}$,

\[
Q^w_i(v, c) \equiv 1 \text{ if } \Phi_{wB}\beta^w(v) \geq \Gamma_i, w_i\beta^w(c_i) = \min_{j \in \mathcal{N}} \Gamma_j, w_j\beta^w(c_j),
\]

and otherwise $Q^w_i(v, c) \equiv 0$ while for the buyer, $Q^w_B(v, c) \equiv \sum_{i \in \mathcal{N}} Q^w_i(v, c)$.

**Proof.** See Appendix B.

An implication of Lemma 1 is that the probability of trade, and hence social surplus, are
increasing in $\beta^w$.

We are left to augment the allocation rule of Lemma 1 with a consistent payment rule.
By the payoff equivalence theorem (see, e.g., [Myerson, 1981] [Krishna, 2002] [Börgers, 2015])
the interim expected payoff of an agent is pinned down by the allocation rule and incentive
compatibility up to a constant that is equal to the interim expected payoff of the worst-off
type for that agent. Incentive compatibility implies further that $v$ and $\tau$ are the worst-off
types of the buyer and suppliers, respectively. Thus, to complete the definition of
incomplete information bargaining, all that remains to be done is to define these constants.

By standard mechanism design arguments (see Appendix A.1), the expected budget
surplus for the mechanism with the allocation rule in Lemma 1 not including the constants
reflecting payments to worst-off types, can be written in terms of the allocation rule and
virtual types as follows:

\[
\pi^w \equiv \sum_{i \in \mathcal{N}} E_{v, c} [(\Phi(v) - \Gamma_i(c_i)) \cdot Q^w_i(v, c)].
\]

Of course, if $\beta^w < 1 / \max \mathbf{w}$, it must be that $\pi^w = 0$, in which case the question of how
to allocate the budget surplus is moot. In contrast, if $\beta^w = 1 / \max \mathbf{w}$, then $\pi^w > 0$ is
possible. In this case, weighted welfare is maximized when $\pi^w$ is allocated among the buyer

---

17 Sometimes, the payoff equivalence theorem is also referred to as the revenue equivalence theorem. However, revenue equivalence is an implication of the payoff equivalence theorem.

18 That is, for any mechanism satisfying incentive compatibility, $\underline{v} \in \arg \min_{v \in [\underline{v}, \overline{v}]} E_{v}[U(v, c)]$ and $\tau \in \arg \min_{v \in [\underline{v}, \overline{v}]} E_{v,c-1}[U_i(v, c)]$. 

10
and suppliers with bargaining weights equal to \(\max \mathbf{w}\). If more than one agent has the maximum bargaining weight, then some “tie breaking” is required. For example, one might apply equal sharing or distribute the surplus according to Nash bargaining weights—as with Nash bargaining weights, the sharing rule has no social surplus effects. We denote the agents’ shares of \(\pi^w\) by \(\eta \in [0, 1]^{n+1}\) satisfying \(\eta_i = 0\) for all \(i\) such that \(w_i < \max \mathbf{w}\) and \(\sum_{i \in \mathcal{N}} \eta_i = 1\), yielding interim expected payoffs to the agents’ worst-off types of

\[
\hat{u}_B(v; \mathbf{w}, \eta_B) = \eta_B \pi^w \quad \text{and} \quad \hat{u}_i(v; \mathbf{w}, \eta_i) = \eta_i \pi^w.
\]

(7)

The outcome of incomplete information bargaining is then given by the expected buyer and supplier payoffs from the price-formation mechanism described above, which, following the mechanism design techniques described in Appendix A.1, can be written as:

**Proposition 1.** Incomplete information bargaining with bargaining weights \(\mathbf{w}\) and shares \(\eta\) generates expected payoffs

\[
u_B(\mathbf{w}, \eta_B) = \hat{u}_B(v; \mathbf{w}, \eta_B) + \mathbb{E}_v \left[ \sum_{i \in \mathcal{N}} \int_v^\infty \mathbb{E}_c [Q^w_i(x, \mathbf{c})] \, dx \right]
\]

and, for \(i \in \mathcal{N}\),

\[
u_i(\mathbf{w}, \eta_i) = \hat{u}_i(v; \mathbf{w}, \eta_i) + \mathbb{E}_{c_i} \left[ \int_{c_i}^{\infty} \mathbb{E}_{v,c_{-i}} [Q^w_i(v, x, \mathbf{c}_{-i})] \, dx \right],
\]

with \(\hat{u}_B(v; \mathbf{w}, \eta_B)\) and \(\hat{u}_i(v; \mathbf{w}, \eta_i)\) satisfying (7).

As we now show, the outcomes from incomplete information bargaining as given in Proposition 1 coincide with the set of Pareto undominated payoffs associated with mechanisms in the set of incentive-compatible, individually-rational, no-deficit mechanisms, which we denote by \(\mathcal{M}\). To see this, take as given a vector of expected payoffs \(\tilde{\mathbf{u}}\) that is the outcome of \(\langle \tilde{\mathbf{Q}}, \tilde{\mathbf{M}} \rangle \in \mathcal{M}\) and that is Pareto undominated in the set of expected payoff vectors that obtain from mechanisms in \(\mathcal{M}\). Then there exist bargaining weights \(\mathbf{w} \in [0, 1]^{n+1}\) such that \(\tilde{\mathbf{Q}}\) is the allocation rule in incomplete information bargaining with weights \(\mathbf{w}\) (as shown in the proof of Proposition 2 these weights are derived from Lagrange multipliers on constraints that each supplier’s payoffs be at least as great as in \(\tilde{\mathbf{u}}\)). Further, there exist shares \(\eta\) such that the agents’ expected payoffs from incomplete information bargaining with bargaining weights \(\mathbf{w}\) and shares \(\eta\) are \(\tilde{\mathbf{u}}\). Conversely, because no money is “left on the table,” any expected payoffs from incomplete information bargaining with weights \(\mathbf{w}\) and shares \(\eta\) are Pareto undominated among payoffs resulting from mechanisms in \(\mathcal{M}\).
Proposition 2. Expected payoff vector \( \tilde{u} \) associated with \( (\tilde{Q}, \tilde{M}) \in M \) is Pareto undominated among expected payoff vectors for mechanisms in \( M \) if and only if there exist bargaining weights \( w \) and shares \( \eta \) such that \( Q^w = \tilde{Q} \) and \( (u_B(w, \eta_B), u_1(w, \eta_1), ..., u_n(w, \eta_n)) = \tilde{u} \).

Proof. See Appendix B.

To illustrate, consider the bilateral trade problem of Myerson and Satterthwaite and assume, for concreteness, that \( v = c = 0 \) and \( \bar{v} = \bar{c} = 1 \). In this case, \( \pi^w = 0 \) for all \( w \), so we can ignore the shares \( \eta \). Incomplete information bargaining with \( w = (1, 0) \) is the buyer-optimal mechanism, which consists of a buyer of type \( v \) making the take-it-or-leave-it offer \( \Gamma^{-1}(v) \) to the supplier. For example, when the agents’ types are uniformly distributed, the buyer offers \( v/2 \), yielding \( u_B(1, 0) = 1/12 \) and \( u_1(1, 0) = 1/24 \). Conversely, for \( w = (0, 1) \), we have the supplier-optimal mechanism. In this mechanism, the supplier with cost \( c \) makes the take-it-or-leave-it offer \( \Phi^{-1}(c) \). For uniformly distributed types, this is \( (c + 1)/2 \), yielding \( u_1(0, 1) = 1/12 \) and \( u_B(0, 1) = 1/24 \). These two points are illustrated as dots in Figure 1(a). One can, of course, use randomized take-it-or-leave-it offers with the buyer (resp. supplier) making the offer with some probability. Thus, any convex combination between \((u_B(1, 0), u_1(1, 0))\) and \((u_B(0, 1), u_1(0, 1))\) is achievable, as indicated by the dashed line in Figure 1(a).

![Figure 1: Panel (a): Buyer and supplier payoffs for randomized take-it-or-leave-it offers and for the k-double auction with k = 1/2. Panel (b): Payoffs in the k-double auction for all k ∈ [0, 1]. Both panels assume that there is one supplier and that the buyer’s value and the supplier’s cost are uniformly distributed on [0, 1].](image-url)

---

19Of course, the assumption of identical supports imposes some restrictions. Given this assumption, setting \( v = 0 \) and \( \bar{v} = 1 \) is an innocuous normalization.
However, one can in general do better than using randomized take-it-or-leave-it offers by allowing the allocation rule to vary with the bargaining weights beyond just being a linear combination of the extremes. Indeed, as is evident from Lemma 1, this is what happens in incomplete information bargaining, whose allocation rule depends on the bargaining weights, and this is also the case for the \( k \)-double auction of Chatterjee and Samuelson (1983). To see this, recall that given \( k \in [0, 1] \), the buyer and supplier in a \( k \)-double auction simultaneously submit bids \( p_B \) and \( p_S \), and trade occurs at the price \( kp_B + (1-k)p_S \) if and only if \( p_B \geq p_S \). By construction, the \( k \)-double auction never incurs a deficit. If the agents’ types are uniformly distributed on \([0, 1]\), then the linear Bayes Nash equilibrium of the \( k \)-double auction results in trade if and only if \( v \geq c \frac{1+k}{2-k} + \frac{1-k}{2} \). As first noted by Myerson and Satterthwaite (1983), for \( k = 1/2 \) and uniformly distributed types, the \( k \)-double auction yields the second-best outcome.

Williams (1987) first observed that for uniformly distributed types and any \( k \in [0, 1] \), the \( k \)-double auction implements the outcomes of a price-formation process with bargaining weights. As we show in Appendix C, incomplete information bargaining includes the \( k \)-double auction described above as a special case. Specifically, assuming one supplier and uniformly distributed types on \([0, 1]\), for any bargaining weights \( w \), there exists \( k \in [0, 1] \) such that the outcome of the \( k \)-double auction is the same as the outcome of the price-formation mechanism with weights \( w \), and conversely, for any \( k \in [0, 1] \), there exist bargaining weights \( w \) such that the price-formation mechanism with weights \( w \) yields the same outcome as the \( k \)-double auction. As intuition for the relation between the \( k \)-double auction and incomplete information bargaining, first note that for the case of one-supplier, the allocation \( Q^w_i(v, c) \) is the same for all \( w \) with the same bargaining differential \( \Delta \) defined by

\[
\Delta \equiv \frac{w_B - w_1}{\max\{w_B, w_1\}} \in [-1, 1].
\]

Thus, we can write the allocation rule as a function of \( \Delta \) rather than of the bargaining weights. A \( k \)-double auction with \( k = 1 \) essentially gives all the bargaining power to the buyer because trade, when it occurs, occurs at the buyer’s bid. This is the same as in the

---

20 It is perhaps worth noting that this reasoning is essentially the same as that invoked by Samuelson (1949) to demonstrate that with constant returns to scale, the production possibility frontier is concave.

21 In the linear Bayes Nash equilibrium, a buyer of type \( v \) bids \( p_B(v) = (1-k)k/(2(1+k)) + v/(1+k) \) and a supplier with cost \( c \) bids \( p_S(c) = (1-k)/2 + c/(2-k) \). For \( k = 1 \), \( p_B(v) = v/2 \) and \( p_S(c) = c \), and for \( k = 0 \), \( p_B(v) = v \) and \( p_S(c) = (c+1)/2 \). Thus, for \( k \in \{0, 1\} \), the \( k \)-double auction reduces to take-it-or-leave-it offers.

22 There is an interesting relation between the effects of equalizing bargaining weights, which is at the center of our analysis, and the effects of equalizing ownership shares in a partnership model à la Cramton et al. (1987). Both effects increase equally weighted social surplus, but, as discussed after Corollary 1 below, for fundamentally different reasons.
price-formation mechanism with $\Delta = 1$, which is the optimal procurement mechanism for the buyer. It follows that the sets of types that result in trade are the same. At the other extreme, a $k$-double auction with $k = 0$ essentially gives all the bargaining power to the supplier, which is the same as in the price-formation mechanism with $\Delta = -1$. In between, a $1/2$-double auction balances the bargaining powers of the two agents, which is also the case in the price-formation mechanism with bargaining parameter $\Delta = 0$. Equalization of bargaining power increases expected social surplus in incomplete information bargaining just as it does in the $k$-double auction.

### 3.2 Social-surplus-increasing equalization of bargaining weights and scope for countervailing power

Despite the result of Proposition 2 that incomplete information bargaining as defined above is Pareto efficient, its outcome may differ from what a social planner who cares about equally weighted socially surplus would like, as we now show. This creates potential for social surplus increasing equalization of bargaining power and scope for countervailing power. Specifically, in what follows, by *equalization* of bargaining power, we mean a change from asymmetric bargaining weights to symmetric bargaining weights, i.e., to weights satisfying $w_B = w_1 = \cdots = w_n$.

The social planner’s problem is to choose $\langle Q, M \rangle$ to maximize

$$E_{v,c}[W_Q(v,c)] \quad \text{s.t.} \quad E_{v,c}[R_M(v,c)] \geq 0.$$  

By the payoff equivalence theorem, incentive compatibility pins down $M$ up to constants by $Q$, and the constants are pinned down and equal to zero by the individual-rationality constraints. Denote by $Q^*$ the allocation rule that solves the planner’s problem, and let

$$W^* \equiv E_{v,c}[W_{Q^*}(v,c)]$$

be the optimized value of the planner’s objective.

We can now contrast the planner’s preferred outcome with the solution to the problem that the *market* solves. We define the market by the agents’ type distributions, bargaining weights $w$, and shares $\eta$. The market’s problem is to choose $\langle Q, M \rangle$ to maximize (5), and the resulting allocation rule is $Q^w$ given by Lemma 1. Letting

$$W^w \equiv E_{v,c}[W_{Q^w}(v,c)]$$
be the value of the planner’s objective under the allocation rule chosen by the market, we have \( W^w \leq W^* \) because the allocation rule \( Q^w \) is available when the planner chooses \( Q^* \). Notice also that \( Q^* = Q^1 \) and, more generally, \( Q^* = Q^{(w,\ldots,w)} \) for any \( w \in (0,1] \). Hence, for any \( w \in (0,1] \), we have \( W^* = W^{(w,\ldots,w)} \).

Given a market with weights \( w \), we say that the planner prefers an equalization of bargaining weights if

\[
W^w < W^*,
\]

or equivalently, \( Q^w(v,c) \neq Q^*(v,c) \) for all \((v,c)\) in an open subset of \([\bar{v},\overline{v}] \times [\bar{c},\overline{c}]^n\). As stated in the next proposition, specific conditions are required for the planner not to prefer an equalization of bargaining weights. Of course, there is no benefit to the planner from equalization if the bargaining weights are already equalized, but even when the weights are not all the same, there is no benefit to the planner if the market has full trade, i.e.,

\[
\max_{i \in N} \Gamma_i(w_i) \beta^w(c_i) \leq \Phi_w B^w(v), \tag{9}
\]

which implies that \( \beta^w = 1/\max w \), and there is sufficient symmetry among the suppliers that it is always the lowest-cost supplier that trades. Specifically, the suppliers must have equal bargaining weights, \( w_1 = \cdots = w_n = w \), and must either have the maximum bargaining weight, \( w = \max w \), so that \( \Gamma_i(w_i) \beta^w(c_i) = c_i \), or it must be that \( G_1 = \cdots = G_n \), so that the supplier with the lowest weighted virtual cost is also the supplier with the lowest actual cost.

**Proposition 3.** In a market with asymmetric bargaining weights \( w \), the planner prefers an equalization of bargaining weights unless all of the following conditions are satisfied:

(i) \( (9) \) holds;

(ii) for all \( i \in N \), \( w_i = w \);

(iii) either \( w_B < w \) or for all \( i \in N \), \( G_i = G \).

**Proof.** See Appendix B.

---

23To see this, note that \( W^{(w,\ldots,w)}_{Q,M}(v,c) = w(W_Q(v,c) - R_M(v,c)) \), which is maximized, subject to no deficit, at \( Q^* \). With symmetric bargaining weights, the weight \( w \) has a multiplicative effect on the solution value of the Lagrange multiplier on the no-deficit constraint, but ultimately it has no effect on the allocation rule \( Q^w \), which depends on \( w \) divided by that multiplier.

24That ex ante symmetry among suppliers implies that there is no inefficiency in production when the production decision is based on (equally weighted) virtual costs rather than costs hinges on the assumption that the virtual cost functions are increasing. Without that assumption, the weighted virtual cost functions would have to be replaced by their “ironed” counterparts (see Myerson 1981), and the resulting allocation rules with induce inefficiencies with positive probability because of random tie-breaking.
While Proposition 3 provides conditions under which the planner prefers an equalization of bargaining weights for a market with given weights $w$, there exist bargaining weights such that if a market were endowed with those weights, then the planner would prefer an equalization of bargaining weights, i.e., $W^w < W^*$, unless $n = 1$, $\bar{c} \leq \Phi(\bar{v})$, and $\bar{v} \geq \Gamma_1(\bar{c})$. Specifically, for $n = 1$, if $\bar{c} > \Phi(\bar{v})$, then giving the supplier all the bargaining power reduces welfare below $W^*$, and if $\bar{v} < \Gamma_1(\bar{c})$, then giving the buyer all the bargaining power reduces welfare below $W^*$.

The results above show that, quite generally, equalization of bargaining power increases social surplus. Some of the benefits that the planner obtains from more equal bargaining weights stem from an equalization of bargaining weights among suppliers, which eliminates socially wasteful discrimination among suppliers based on differently weighted virtual costs. While this effect is integral to the incomplete information bargaining model that we study here, equalization of bargaining power on one side of the market is arguably not what competition authorities and practitioners, or for that matter, John Galbraith, have in mind when speaking of countervailing power, which refers to an equalization of bargaining power across the two sides of the market. Adhering to this terminology, we say that there is scope for countervailing power in a market if the planner prefers an equalization of bargaining power across the two sides of the market.

To analyze the scope for countervailing power, we therefore focus on the case in which suppliers have symmetric bargaining weights, that is, $w_1 = ... = w_n$. In this case, payoffs are pinned down by the bargaining differential between the buyer side of the market and the supplier side of the market as captured by $\Delta$ given in (8). This allows us to write every agent’s ex ante expected surplus as a function of $\Delta$ only. Denoting by $u_S(\Delta) \equiv \sum_{i \in N} u_i(\Delta)$ aggregate expected supplier surplus when the bargaining weights of the two sides differ by $\Delta$, we can trace out the frontier of expected buyer and expected aggregate supplier surplus, which we refer to as the Williams frontier in honour of Williams (1987), who first studied this frontier in a model with one buyer and one supplier. Formally, the Williams’ frontier is defined as

$$\mathcal{F} \equiv \{(u_S(\Delta), u_B(\Delta)) \mid \Delta \in [-1,1]\},$$

with associated mapping $\omega : [u_S(1), u_S(-1)] \rightarrow [u_B(-1), u_B(1)]$ defined by $\omega(u) = \max\{y \mid (u, y) \in \mathcal{F}\}$. For the special case of $n = 1$ and uniformly distributed types, the Williams frontier coincides with the payoff frontier for the $k$-double auction, which is depicted in

\[25\] These distributional assumptions are restrictive in the sense that they are not satisfied if the supports of the buyer’s and suppliers’ type distributions overlap because $\Phi(v) < v$ for any $v < \bar{v}$ and $\Gamma_i(c) > c$ for any $c > \bar{c}$. Further, the conditions fail in many cases even when there is no overlap—for example, if the supplier draws its cost from the uniform distribution on $[0, 1]$ and $F(v)$ is uniform on $[v, v + 1]$, then the conditions hold if and only if $v \geq 2$. 

16
Figure 1(b). The frontier there is concave to the origin, which as shown next is a general property:

**Proposition 4.** The Williams frontier is concave to the origin, i.e., \( \omega(\cdot) \) is strictly decreasing and concave, and strictly concave if there is at most one value of \( \Delta \) that achieves the first-best.

**Proof.** See Appendix B.

The concavity of the Williams frontier follows a logic that is reminiscent of Samuelson’s (1949) argument that the production possibility frontier is concave under constant returns to scale. The price-formation mechanism could randomize over the mechanism that is optimal for the buyer and the mechanism that is (jointly) optimal for suppliers. Hence, any linear combination between \((u_S(1), u_B(1))\) and \((u_S(-1), u_B(-1))\) can be achieved. This corresponds to the thought experiment of Samuelson whereby equal proportions of all inputs are shifted from one sector to another, with which, in his words, a “neophyte bureaucrat might be satisfied” (Samuelson, 1949, pp. 184–185). However, in general, one can do better by reoptimizing.

Building on this, the concavity of the Williams frontier has the following implication:

**Corollary 1.** A change in the buyer-side and supplier-side bargaining weights that moves them closer together, i.e., that moves \( \Delta \) closer to zero, weakly increases social surplus: if \( \Delta' < \Delta \leq 0 \) or \( 0 \leq \Delta < \Delta' \), then

\[
u_B(\Delta') + u_S(\Delta') \leq u_B(\Delta) + u_S(\Delta) \leq u_B(0) + u_S(0) .
\]

Picking up on a comment made above, an effect similar to that described in Corollary 1 arises in the partnership literature, where social surplus is increased by equalizing ownership shares rather than by equalizing bargaining weights. For example, as first observed by Cramton et al. (1987), when all agents draw their values independently from the same distribution, ex post efficient reallocation is possible if all agents have equal shares, and is impossible if one agent has full ownership. However, the paths through which these gains in social surplus are achieved, and the gains themselves, are different in the two approaches. In the partnership literature, the allocation rule is kept fixed at the ex post efficient one, but agents’ ownership shares are allowed to change. The revenue of the mechanism increases as ownership shares (or, more generally, agents’ worst-off types) become more similar, eventually permitting the first-best without running a deficit.\(^{26}\) In contrast, in incomplete information bargaining with

---

\(^{26}\)With identical distributions, equal shares imply equal worst-off types, which somewhat camouflages the point that the driving force for possibility is the equalization of worst-off types; see, for example, Che (2006) for a proof that with equal worst-off types, ex post efficiency is possible.
bargaining weights, the worst-off types of all agents are always the same (the lowest type for a buyer and the highest type for a supplier), and so is the budget surplus of the mechanism, which is zero. What changes as the bargaining weights change is the allocation rule, which transitions from, say, the buyer-optimal one via the second-best to the one that is optimal for the suppliers. Moreover, because, for example with identical supports, the second-best is different from first-best in the model with bargaining weights, equalization of bargaining weights yields, in general, less social surplus than equalization of ownership shares (or worst-off types) in a partnership model.

3.3 Implementation

In many cases, economists have achieved greater comfort with models of price-formation processes when the literature has shown that there exists a noncooperative game that, at least under some assumptions, has as an equilibrium outcome that is the same as the outcome delivered by the model under consideration. Indeed, this comfort often extends well beyond the narrow confines of the foundational game. For example, to support the model of perfectly competitive markets, one might view price-taking buyers and suppliers as submitting demand and supply schedules to a (fictitious) Walrasian auctioneer who then sets market clearing pricing. Similarly, in the Cournot model, one might view firms as submitting quantities to an auctioneer or market maker who sets the market clearing price. Under assumptions on the alternation of offers and taking the limit as the time between offers goes to zero, Rubinstein bargaining delivers Nash bargaining outcomes (Rubinstein, 1982); and under additional assumptions, including conditions on firms’ marginal contributions and passive beliefs, the limit of an alternating-offers game approximates Nash-in-Nash outcomes (Collard-Wexler et al., 2019).

In light of this, it is perhaps useful to note that, as discussed in Section 3.1, for the case of one supplier and uniformly distributed types, the $k$-double auction of Chatterjee and Samuelson (1983) provides an extensive-form game that delivers the same outcomes as incomplete information bargaining. In addition, in the online appendix, we show that our approach has axiomatic foundations analogous to those that underpin Nash bargaining.

As we discuss now, for general distributions and any number of suppliers, the incomplete information bargaining outcome arises in equilibrium in an extensive-form game involving a buyer, suppliers, and a fee-setting broker. Building on the model of Loertscher and Niedermaier (2019), we define the fee-setting extensive-form game to have one buyer, $n \geq 1$.

---

27Microfoundations of the Cournot model along the lines of Kreps and Scheinkman (1983), while dispensing with the assumption of an auctioneer, maintain the assumption of an exogenously given price-formation process by postulating that firms first choose capacities and then prices.
suppliers, and an intermediary that facilitates the buyer’s procurement of inputs from the suppliers and that charges the buyer a fee for its service. The buyer’s value and the suppliers’ costs are not known by the intermediary, although the intermediary does know the distributions $F$ and $G_1, \ldots, G_n$ from which those types are independently drawn. The timing is as follows: 1. the intermediary announces (and commits to) a discriminatory clock auction, which we define below, and fee schedule $(\sigma_1, \ldots, \sigma_n)$, where $\sigma_i$ maps the price $p$ paid by the buyer to supplier $i$ to the fee $\sigma_i(p)$ paid by the buyer to the intermediary, if the buyer purchase from supplier $i$; 2. the buyer sets a reserve $r$ for the auction; 3. the intermediary holds the auction with reserve $r$, which determines the winning supplier, if any, and the payment to that supplier; 4. given winner $i$ and payment $p$, supplier $i$ provides the good to the buyer, and the buyer pays $p$ to supplier $i$ and $\sigma_i(p)$ to the intermediary. If no supplier bids below the reserve, then there is no trade and no payments are made, including no payment to the intermediary.

As just mentioned, the intermediary uses a discriminatory clock auction with reserve $r$. Because this is a procurement, it is a descending clock auction, with the clock price starting at the reserve $r$ and descending from there. As in any standard clock auction, when the clock price changes, participants choose when to exit, and when they exit, they become inactive and remain so. The clock stops when only one active bidder remains, with ties broken by randomization. A discriminatory clock auction specifies supplier-specific discounts off the final clock price $(\delta_1, \ldots, \delta_n)$, where $\delta_i$ maps the clock price to supplier $i$’s discount—activity by supplier $i$ at a clock price of $\hat{p}$ obligates supplier $i$ to supply the product at the price $\hat{p} - \delta_i(\hat{p})$. By the usual clock auction logic, in the essentially unique equilibrium in non-weakly-dominated strategies, supplier $i$ with cost $c_i$ remains active in the auction until the clock price reaches $\hat{p}$ such that $\hat{p} - \delta_i(\hat{p}) = c_i$, and then supplier $i$ exits. We assume that the suppliers follow these strategies.

Turning to the incentives of the buyer and intermediary, the buyer chooses the reserve to maximize its expected payoff, and the intermediary chooses the auction discounts and the fee structure to maximize the expected value of its objective. To allow for the possibility that the intermediary has an interest in promoting the surplus of the agents, we assume that the intermediary’s objective is to maximize expected weighted welfare subject to no deficit, with surplus distributed according to shares $\eta$, where we refer to $w$ in this context as intermediary preference weights and $\eta$ as profit shares.

As we show in the following proposition, the outcome of incomplete information bargaining arises as a Bayes Nash equilibrium of this game:

**Proposition 5.** The outcome of the price-formation mechanism with bargaining weights $w$ and shares $\eta$ is a Bayes Nash equilibrium outcome of the fee-setting extensive-form game.
with intermediary preference weights \( w \) and profit shares \( \eta \).

Proof. See Appendix B.

Thus, the fee-setting extensive-form game, in which a fee-setting intermediary procures an input for the buyer from competing suppliers, provides a microfoundation for the price-formation mechanism. Reminiscent of Crémer and Riordan (1985), the sequential nature of the game allows an equilibrium that is Bayesian incentive compatible for one agent, the buyer, and dominant-strategy incentive compatible for the other agents, the suppliers. The equilibrium of the fee-setting game satisfies ex post individual rationality for both the buyer and suppliers, but only balances the intermediary’s budget in expectation. In contrast, in Crémer and Riordan (1985), the budget is balanced ex post, but only the interim individual rationality constraint is satisfied for the buyer.

To illustrate the fee-setting extensive-form game, we return to the setup with one supplier and uniformly distributed types, where the price-formation mechanism coincides with a \( k \)-double auction. In that case, conditional on trade and a payment \( p \) to the supplier, the buyer’s equilibrium fee to the intermediary is linearly decreasing in \( p \). For example, recalling \( \Delta \) as defined in (8), if \( \Delta = 1 \), then the fee is zero, which implies that when trade occurs, which for this case is when \( 2c \leq v \), the buyer pays \( \frac{v}{2} \) to the supplier and nothing to the intermediary. This is the same outcome as in the \( k \)-double auction with \( k = 1 \), in which case the buyer bids \( \frac{v}{2} \), the supplier bids \( c \), and the buyer’s bid determines the amount paid conditional on trade. For \( \Delta \in [-1, 1) \), the expected buyer and supplier payoffs are the same in the fee-setting extensive-form game as in the corresponding \( k \)-double auction.\(^{28}\)

4 Merger review

In this section, we analyze horizontal mergers and vertical integration. Throughout this section, we assume that after horizontal or vertical integration, the integrated entity can efficiently solve its internal agency problem, which is a standard assumption.\(^{29}\) We evaluate outcomes from an ex ante perspective, that is, before firms’ types are realized. This includes the profitability of mergers or vertical integration.

\(^{28}\)For example, if \( \Delta = -1 \), then we have \( \sigma(p) = \frac{1}{2} - \frac{3}{4}p \), which implies trade occurs when \( c \leq 2v - 1 \), in which case the buyer pays \( 2v - 1 \) to the supplier and \( \sigma(2v - 1) = \frac{1}{2} - \frac{3}{2}v \) to the intermediary. Thus, the supplier’s expected payoff is \( 1/12 \), the buyer’s expected payment to the intermediary is zero, and the buyer’s expected payoff is \( 1/24 \), just as in the \( k \)-double auction with \( k = 0 \).

\(^{29}\)This assumption can be rationalized, for example, on the grounds that integration slackens the individual rationality constraints within the integrated firm.
4.1 Horizontal mergers

We focus on mergers of two suppliers that before the merger are symmetric, both with respect to their distributions and their bargaining weights. Let $G$ denote this distribution with density $g$ and weighted virtual cost $\Gamma_a(c) \equiv c + (1 - a)G(c)/g(c)$.

As stated in Section 2, the merged entity draws its cost from the distribution $\hat{G}(c)$ defined in (1), which, for the case of symmetric merging suppliers, simplifies to $\hat{G}(c) = G(c)(2 - G(c))$. The weighted virtual type function of the merged entity is denoted $\hat{\Gamma}_a(c) \equiv c + (1 - a)\hat{G}(c)/\hat{g}(c)$ and satisfies for any $c \in (c, \overline{c})$ and any $a \in [0, 1)$,

$$\hat{\Gamma}_a(c) = c + (1 - a)\frac{G(c)}{g(c)} \frac{2 - G(c)}{2(1 - G(c))} > c + (1 - a)\frac{G(c)}{g(c)} = \Gamma_a(c).$$

(10)

We assume that for any $a \in [0, 1]$, $\hat{\Gamma}_a(c)$ and $\Gamma_a(c)$ are increasing. Letting $c_i$ and $c_j$ be the cost realizations of suppliers $i$ and $j$ who draw their costs from $G$, we have

$$\hat{\Gamma}_a(\min\{c_i, c_j\}) \geq \Gamma_a(\min\{c_i, c_j\}) = \min\{\Gamma_a(c_i), \Gamma_a(c_j)\},$$

(11)

where the inequality, which is strict unless $a = 1$ or $\min\{c_i, c_j\} = \underline{c}$, follows from (10), and the equality follows from the monotonicity of the virtual type functions.

**Productive power effects**

We begin by holding bargaining power fixed and considering a merger between suppliers 1 and 2 with common bargaining weight $w_1$ and distribution $G_1$. We assume that the merged entity inherits the bargaining weight $w_1$ and that all other bargaining weights remain fixed. Denote by $\beta^w$ the budget parameter in the pre-merger market and by $\hat{\beta}^w$ the budget parameter in the post-merger market. It follows from (11) that, for all $c_1, c_2 \in (\underline{c}, \overline{c})$,

$$\hat{\Gamma}_{w_1\hat{\beta}^w}(\min\{c_1, c_2\}) \geq \Gamma_{w_1\beta^w}(\min\{c_1, c_2\}) = \min\{\Gamma_{w_1\beta^w}(c_1), \Gamma_{w_1\beta^w}(c_2)\},$$

(12)

with equality if and only if $w_1\hat{\beta}^w = 1$ or $\min\{c_1, c_2\} = \underline{c}$.

If the pre-merger market is characterized by $\beta^w < 1/\max w$, then using (12), absent any adjustment to $\beta^w$, the merger results in an increased virtual cost for the merged entity relative to the lower of the virtual costs of the pre-merger suppliers, which reduces the probability of trade by the merging suppliers and reduces revenue to the mechanism. Because $\beta^w < 1/\max w$ implies that the pre-merger mechanism’s expected surplus (not including payments to worst-off types) is zero, i.e., $\pi^w = 0$, the reduction in the probability of trade pushes this below zero, implying that a decrease in the budget parameter is required to
avoid a deficit. Thus, \( \hat{\beta}^w < \beta^w \), further reducing the probability of trade. It follows that given a pre-merger market with \( \beta^w < 1/\max w \), a merger reduces both the buyer’s expected surplus and expected social surplus. Rivals to the merging suppliers benefit from the increase in the merging suppliers’ virtual cost; however, the decrease in the budget parameter and associated overall reduction in trade harms the rivals, so the overall effect of the merger on rivals depends on the details of the specification. Interestingly, the effect of a merger on the merging parties can also go either way, depending on which dominates: the benefit from the reduction in competition and associated increased payments conditional on trade, or the cost associated with the reduced probability of trade.

In contrast, in the boundary case in which \( w_1 \beta^w = w_1 \hat{\beta}^w = 1 \), the weighted virtual cost for the merged entity is simply the minimum of the costs of the merging suppliers, and so the merger does not affect the quantities traded—for the buyer and rivals, the probability of trade is not affected, and for the merged entity, the probability of trade is equal to the sum of the pre-merger probabilities of trade by the merging suppliers. As a result, the merger is neutral for social surplus. To analyze payments, take the pre-merger shares \( \eta \) as given and assume that these shares remain fixed in the post-merger market with the merged entity receiving share \( \eta_1 + \eta_2 \). By the payoff equivalence theorem, we can consider the dominant-strategy implementation of the price-formation mechanism. Ignoring payments to worst-off types, the payment by the buyer to the mechanism and by the mechanism to rivals of the merging suppliers are not affected by the merger. But when the merged entity trades and, say, supplier 1 would have traded in the pre-merger market, the suppression of supplier 2’s bid implies that the payment from the mechanism increases from \( \min_{j \in N \setminus \{1, 2\}} \{ \Phi_{w_B}(v), c_2, \Gamma_{j,w_j}(c_j) \} \) to \( \min_{j \in N \setminus \{1, 2\}} \{ \Phi_{w_B}(v), \Gamma_{j,w_j}(c_j) \} \). Thus, the surplus that accrues to the mechanism and that the mechanism disburses to the agents according to shares \( \eta \) decreases. It follows that the merger is neutral for the buyer with \( w_B < \max w \), whose worst-off type has interim expected payoff of zero, and otherwise harms the buyer. The effects of the merger on the suppliers can go either way, depending on the specification.

In the remaining cases, in which \( w_1 < \max w \) or \( \hat{\beta}^w < 1/\max w \), it follows from (12) that a merger reduces trade by the merging suppliers, which harms the buyer and society;

30 The buyer’s threshold payment pre-merger is \( \Phi_{w_B}^{-1}(\min_{i \in N} \Gamma_{i,w_i,\beta^w}(c_i)) \) and after the merger is \( \Phi_{w_B}^{-1}(\hat{\Gamma}_{1,w_1,\hat{\beta}^w}(\min\{c_1, c_2\}), \min_{j \in N \setminus \{1, 2\}} \Gamma_{j,w_j,\hat{\beta}^w}(c_j)) \), which is the same if \( w_1 \beta^w = w_1 \hat{\beta}^w = 1 \). A similar argument applies to the rivals.

31 It is possible for the merger to be profitable for the merging suppliers but harm the rivals. For example, suppose that \( \beta^w = \beta^w = 1/\max w \) and \( \pi^w > 0 \), and suppose that for some nonmerging supplier \( i \), we have \( w_i = \max w \) and \( \eta_i > 0 \). Assuming that the merger leaves bargaining weights and shares unaffected, if the merger occurs between two suppliers with the maximum bargaining weight, then the merger harms supplier \( i \) because \( \eta_i \hat{\pi}^w < \eta_i \pi^w \), where \( \hat{\pi}^w \) is the post-merger counterpart to \( \pi^w \), and hence the fixed payment to supplier \( i \)’s worst-off type is reduced.
however, as before, the effects on rivals and the merging suppliers can go either way.

We summarize with the following proposition:

**Proposition 6.** Considering only productive power effects associated with a merger of symmetric suppliers with bargaining weight $w$, if $w\beta^w = w\hat{\beta}^w = 1$, then the merger is neutral for social surplus, and if in addition $\eta_B = 0$, then also for the buyer; otherwise, the merger reduces expected buyer surplus and expected social surplus.

Proposition 6 tells us that, except in boundary cases, the productive power effects of a merger of symmetric suppliers harm the buyer and society. Proposition 6 generalizes the insights from Loertscher and Marx (2019) to a setting in which incomplete information pertains to both sides of the market and bargaining power is not restricted to be with the buyer. However, as we analyze next, the effect of a merger on social surplus can go the other way if bargaining power itself is affected by the merger.

**Countervailing power effects**

The question of whether a merger can be defended on the grounds that it endows merging parties with countervailing power that somehow “levels the playing field” features prominently in concurrent antitrust debates and cases. As a case in point, the Australian government’s 1999 (now superseded) guidelines stated: “If pre-merger prices are distorted from competitive levels by market power on the opposite side of the market, a merger may actually move prices closer to competitive levels and increase market efficiency. For example, a merger of buyers in a market may create countervailing power which can push prices down closer to competitive levels” (ACCC, 1999, para. 5.131). Ho and Lee (2017) find evidence of countervailing power, estimating that mergers among insurers increase the insurers’ bargaining power in negotiations with hospitals. Based on an analysis of hundreds of mergers, Bhattacharyya and Nain (2011, p. 99) find outcomes that are “consistent with the creation of buyer power through downstream consolidation to countervail upstream market power.”

Despite the relevance of the issue, a major obstacle to analyzing the effects of countervailing power in existing modeling approaches is that these take the efficiency of the price-formation process as given. This is true for all oligopoly models, in which agents on one side of the market (typically buyers) are assumed to be price-takers. It also applies to the randomized take-it-or-leave-it offers model that give rise to the straight line in Figure 1(a). In contrast, as illustrated in Figure 1(b), if the equalization of bargaining weights changes the price-formation process from, for example, one based on take-it-or-leave-it offers to one based on a $k$-double auction with $k = 1/2$, then a change in bargaining weights has an impact on social surplus. The price-formation mechanism that we study captures the effects...
of bargaining weights on social surplus because the efficiency of the mechanism varies with bargaining weights.

If a merger leads to an equalization of bargaining power in the post-merger market, then the merger combined with the equalization of bargaining power increases efficiency if the bargaining power effects outweigh the effects of consolidation. As an example, Figure 2(a) shows a case in which a merger reduces social surplus if the buyer has all the bargaining power both before and after the merger, but a merger increases social surplus if the buyer and suppliers’ bargaining weights are equalized after the merger. Indeed, Figure 2(b) provides an example in which countervailing power restores the first-best in the post-merger market—specifically, if the buyer has all the bargaining weight prior to the merger, then the pre-merger outcome is not the first-best, but with symmetric bargaining weights in the post-merger market, the outcome is the first-best.

Figure 2: Payoff frontiers for the case of 2 symmetric pre-merger suppliers (blue) and 1 post-merger supplier (orange). We assume that in the pre-merger market, \( w_1 = w_2 \), and that the merged entity also has bargaining weight \( w_1 \). We assume equal shares among agents with the maximum bargaining weight. The bargaining power differential for the pre-merger market is denoted by \( \Delta \equiv (w_B - w_1)/\max w \) and for the post-merger market by \( \hat{\Delta} \equiv (w_B - w_1)/\max w \). Panel (a) assumes that the buyer’s and pre-merger suppliers’ types are uniformly distributed on \([0,1]\). Panel (b) assumes that the pre-merger suppliers’ costs are uniformly distributed on \([0,1]\) and that the buyer’s value is uniformly distributed on \([1,2]\). In each case, the merged entity’s cost distribution is given by \([1]\).

We summarize with the following result:

**Corollary 2.** A merger combined with an equalization of bargaining weights between the buyer and seller sides of the market is no more harmful to expected social surplus than the
same merger with no change in bargaining weights and, in some settings, increases expected social surplus, including sometimes to the first-best.

Corollary 2 raises the possibility of a countervailing power defense for a merger. A merger that only involves productive power effects reduces social surplus if the first-best is not possible post merger. In contrast, a merger that causes bargaining weights to shift in favor of the suppliers may improve expected social surplus despite the adverse productive power effects. Of course, a merger with countervailing power is bad for the buyer for two reasons: competition among suppliers is reduced and the remaining suppliers have increased bargaining power. Thus, merger review based on a buyer-surplus standard would never be moved by a countervailing power defense. In contrast, merger review based on a social-surplus standard may well be.

Our analysis allows us to identify necessary conditions for a countervailing power defense. First, as just mentioned, the objective of the merger review would need to include the promotion of social surplus, and not just buyer surplus. Second, the buyer would need to have greater bargaining power than the suppliers prior to the merger, so that movement towards the equalization of bargaining power is possible. Third, the buyer would need to retain at least some bargaining power following the merger—buyer power would need to diminish, but not vanish—so that society is not simply trading a dominant buyer for dominant suppliers.

This brings to mind the EC merger guidelines, which state that “it is not sufficient that buyer power exists prior to the merger, it must also exist and remain effective following the merger. This is because a merger of two suppliers may reduce buyer power if it thereby removes a credible alternative” (EC Guidelines, para. 67). Our conclusions are consistent with that view insofar as the buyer must have power before a merger and retain at least some power after a merger in order for a countervailing power defense to make economic sense.

The necessary conditions for a countervailing power defense raise the question of how one would ascertain that a buyer has bargaining power. For example, if a market is characterized as a $k$-double auction, then evidence of buyer power would be that transactions always occur

\[\text{32In the alternative, but analogous, setting of a sale auction with one supplier and multiple buyers, a merger of buyers harms the supplier and possibly benefits (all) buyers. This gives rise to the possibility of buyer-surplus-increasing mergers, which might be viewed as procompetitive. To increase social surplus, the merger would have to reduce the supplier’s bargaining power without eliminating it.}\]

\[\text{33The EC merger guidelines state, “Countervailing buyer power in this context should be understood as the bargaining strength that the buyer has vis-à-vis the seller in commercial negotiations due to its size, its commercial significance to the seller and its ability to switch to alternative suppliers” (EC Guidelines, para. 64).}\]
at the buyer’s price. For a procurement auction, evidence consistent with buyer power but inconsistent with the absence of buyer power includes: (i) the buyer uses procurement methods that result in suppliers other than the lowest-cost supplier winning, such as handicaps or preferences; (ii) the distribution of the reserve prices is different across the markets if the buyer purchases in separate markets; (iii) one observes with positive probability ties in procurement outcomes and randomization over winners.

4.2 Vertical integration

We now analyze vertical integration between the buyer and one of the suppliers. Following vertical integration between the buyer and supplier $i$, the price-formation mechanism works as before, with the exception that the vertically integrated firm now acts as a buyer with value $y = \min\{v, c_i\}$, whose distribution we denote by

$$\hat{F}(y) \equiv F(y) + G_i(y)(1 - F(y)).$$

If there is no trade between the vertically integrated firm and the nonintegrated suppliers, then the integrated firm has payoff equal to $\max\{0, v - c_i\}$ due to internal sourcing, and the nonintegrated suppliers have payoffs of zero. Observe that for $y \in [v, \bar{v}]$, we have $\hat{F}(y) \geq F(y)$. Thus, vertical integration makes the buyer productively less powerful.

Consider first a bilateral trade setting with overlapping supports before integration (i.e., $n = 1$ and $v < \bar{c}$). Because ex post efficient trade is impossible when the buyer and supplier are independent entities, it follows immediately from our assumption that the integrated entity can resolve the internal agency problem that vertical integration can increase social surplus:

**Proposition 7.** With one supplier and overlapping supports, vertical integration increases social surplus (to the first-best) regardless of bargaining weights.

---

34Note that this property does not hinge on particular distributional assumptions. For $k = 1$, the buyer’s and seller’s optimal bids are $\Gamma_1^{-1}(v)$ and $c$, respectively, while for $k = 0$, they are $v$ and $\Phi^{-1}(c_1)$. Hence, for $k = 1$ ($k = 0$) the $k$-double auction is the mechanism that is optimal for the buyer (seller) for any distributions $F$ and $G_i$ with positive densities on their supports. (If $\Phi$ or $\Gamma_1$ is not monotone, one would replace the virtual type function with its ironed counterparts and the inverse with the generalized inverse (Myerson, 1981).)

35The background for these conditions is as follows. (i): A buyer with power discriminates among heterogeneous suppliers based on their virtual costs. (ii): A buyer without power would optimally set a reserve equal to its value, so even if suppliers in the different markets draw their types from different distributions, the distribution of reserves would be the same across the markets as long as the buyer’s values for the goods in the markets are drawn from the same distribution. (iii): For a buyer with power, this outcome arises when suppliers draw their costs from distributions that are identical but do not satisfy regularity, that is, their virtual costs are not monotone and so the optimal mechanism involves “ironing.” A buyer without power purchases from the lowest-cost supplier.
By Proposition 7, vertical integration can increase social surplus and enable the first-best by essentially eliminating a Myerson-Satterthwaite problem. However, as we show next, it can also create one.

To this end, assume that there are multiple suppliers and consider the case with nonoverlapping supports. The latter assumption implies that prior to vertical integration, ex post efficient trade is possible and, indeed, occurs if the pre-integration bargaining weights are symmetric. Hence, vertical integration cannot possibly increase social surplus. This leaves the question of whether vertical integration could be neutral. The following proposition shows that the answer is negative.

**Proposition 8.** With two or more suppliers and nonoverlapping supports, vertical integration decreases social surplus whenever pre-integration bargaining weights are symmetric, regardless of post-integration bargaining weights.

**Proof.** See Appendix B.

Proposition 8 provides a clear-cut case in which vertical integration is harmful from the perspective of society. This result, as well as the result in Proposition 7, is robust in that it does not depend on specific assumptions about distributions or beliefs of agents. Indeed, because there is always a dominant strategy implementation of the price-formation mechanism, beliefs play no role. Moreover, we obtain social surplus decreasing vertical integration without imposing any restrictions on the contracting space and without invoking exertion of market power by any player (above and beyond requiring individual-rationality and incentive-compatibility constraints to be satisfied). These are noticeable differences relative to the post-Chicago school literature on vertical contracting and integration, whose predictions rely on assumptions about beliefs, feasible contracts, and/or market power. Of course, our results do rely, inevitably, on support assumptions.

At the heart of both Propositions 7 and 8 is the fact that the efficiency of the price-formation process is endogenous in incomplete information bargaining. The elimination of a Myerson-Satterthwaite problem through vertical integration is the incomplete-information analogue to the classic double mark-up problem. In contrast to the literature, however, there is now a new effect, namely that the market with the remaining suppliers becomes less efficient. Further, it is possible for this latter effect to dominate so that the market as a whole is made less efficient as a result of vertical integration.  

---

36 For an overview, see Riordan (2008). On the sensitivity of complete information vertical contracting results to assumptions of “symmetric,” “passive,” and “wary” beliefs see, e.g., McAfee and Schwartz (1994).

37 This occurs, for example, with $n = 2$ and symmetric bargaining weights if $F$ is uniform on $[0, 1]$ and for $i \in \{1, 2\}$, $G_i(c) = c^{1/10}$, also with support $[0, 1]$. Then vertical integration causes social surplus to decrease from 0.4827 to 0.4815.
Connecting bargaining breakdown with vertical integration

A pervasive feature of real-world bargaining is that negotiations often break down. Anecdotal examples range from the U.S. government shut down, to the British coal miners’ and the U.S. air traffic controllers’ strikes in the 1980s, to failures to form coalition governments in countries with proportional representation, to, possibly, Brexit. Providing systematic evidence of bargaining breakdown, Backus et al. (2020) analyze a data set covering 25 million observations of bilateral negotiations on eBay and find a breakdown probability of roughly 55 percent.

In incomplete information bargaining, negotiations break down on the equilibrium path for two reasons. First, it may be that the buyer’s value is below the supplier’s cost, but because of private information, the two parties do not know this before they sit down at the negotiating table, so bargaining begins but then breaks down. Second, with unequal bargaining power, incentives for rent extraction may lead more powerful agents to impose sufficiently aggressive thresholds for trade that breakdown results. Third, by the Myerson-Satterthwaite theorem, even if the buyer’s value exceeds the supplier’s cost, the constraints imposed by incentive compatibility, individual rationality, and no deficit may prevent ex post efficient trade from taking place.

Assuming that real-world negotiations are appropriately captured by incomplete information bargaining, one can use observed frequencies of negotiation breakdowns to back out the parameters of the distributions from which the buyer and the supplier draw their types. For purpose of illustration, we assume in the following that the buyer’s value and the sellers’

---

38As described by Crawford (2014), there are regular blackouts of broadcast television stations on cable and satellite distribution platforms due to the breakdown of negotiations over the terms for retransmission of the broadcast signal.
cost are drawn from parameterized distribution

\[ F(v) = 1 - (1 - v)^{1/\kappa} \quad \text{and} \quad G_i(c) = c^{1/\kappa_i} \quad \text{with support} \quad [0, 1], \quad (13) \]

where the parameters \( \kappa \) and \( \kappa_i \) are positive real numbers and have the interpretation of “capacities” insofar as larger values of \( \kappa \) and \( \kappa_i \) imply better distributions in the sense of first-order stochastic shifts. These distributions are analytically convenient because they imply linear virtual type functions. Figure 3 plots the probability that negotiations break down as a function of \( \kappa \) under the assumptions that \( n = 1, \kappa_1 = \kappa \), and \( w_B = w_1 \). For example, if, as in the data set of Backus et al. (2020), 55 percent of all negotiations break down, eyeballing the figure indicates that \( \kappa \) must be around 1.5. Rather than treating negotiation breakdowns as measurement error, which is difficult to justify if breakdown occurs more than fifty percent of the time in 25 million observations, the frequency of those breakdowns is valuable information that can be used for estimation in the incomplete information framework.

Pre-integration market conditions, particularly the probability of breakdown, can also be used to gauge the social surplus effects of vertical integration. To see this, assume that \( n = 2 \) in the market before integration by the buyer with supplier 1, \( w \) and \( \eta \) are symmetric, and \( F \) and \( G_i \) are given by (13). As an identifying assumption, stipulate that \( (\kappa_1 + \kappa_2)/2 = 1 \), that is, the suppliers’ capacities are equal to one on average (alternatively one might use, e.g., margin data for identification). Figure 4(a) shows the results of the calibration of these parameterized distributions given data on supplier market shares and the probability of bargaining breakdown.

(a) Calibration of distributions to data

(b) Change in social surplus following vertical integration

Figure 4: Interaction between the pre-integration breakdown probability and the effect of vertical integration on social surplus. Panel (a): Calibration of distributional parameters based on market shares and breakdown probabilities assuming that \( n = 2, w \) and \( \eta \) are symmetric, \( F(v) \) and \( G_i(c) \) are given by (13), and \( (\kappa_1 + \kappa_2)/2 = 1 \). Panel (b): Change in social surplus due to vertical integration as the probability of breakdown in the pre-integration market, “pre-VI Pr(bd),” varies, based on the calibration of Panel (a).

\[ ^{39} \text{More precisely, for the case considered, a breakdown probability of 55 percent corresponds to } \kappa = 1.6090. \]
Now consider the effect on social surplus of vertical integration assuming that there are two pre-integration suppliers with equal market shares and assuming that bargaining weights are symmetric both before and after integration. As illustrated in Figure 4(b), in markets where before integration the probability of breakdown is low, the change in social surplus from vertical integration is negative. In that case, the reduced efficiency of price formation with the independent supplier dominates the gain in efficiency associated with internal transactions, and vertical integration reduces social surplus. In contrast, when the probability of breakdown is high prior to integration, then the increased efficiency of internal transactions dominates, and social surplus increases as a result of vertical integration.

5 Extensions

In this section, we extend the model three ways. First, we include investment and derive results that highlight the tight connection between the efficiency of incomplete information bargaining and the incentives to invest. Second, we allow the agents to have heterogeneous outside options and show that some but not all of the intuition from complete information bargaining on outside options carries over to incomplete information bargaining. Finally, we allow for multi-object demand by the buyer and supplier-specific preferences and show that in that case, bargaining externalities naturally arise.

5.1 Investment

Investment incentives feature prominently, and at times controversially, in concurrent policy debates. They have been at center stage in the theory of the firm since Grossman and Hart (1986) and Hart and Moore (1990) (G-H-M hereafter). To account for investment, we extend our model by adding investment as an action taken by each agent prior to the realization of private information, where investment improves an agent’s type distribution.

We show that the results under incomplete information differ starkly from those obtained in the G-H-M literature. This literature stipulates complete information and efficient bargaining and, as a consequence, obtains hold-up and inefficient investment. In contrast, in our setting, incomplete information protects agents from hold-up, and investments are efficient if and only if bargaining is efficient.

We suppose that the buyer and each supplier can improve (or more generally change) their type distributions by investing \( e_j \) at cost \( \Psi_j(e_j) \) for agent \( j \in \{B\} \cup N \). Consistent with

\[40\] For example, related to the 2017 Dow-DuPont merger, the U.S. DOJ’s “Competitive Impact Statement” identifies reduced innovation as a key concern (https://www.justice.gov/atr/case-document/file/973951/download, pp. 2, 10, 15, 16).
G-H-M, we assume that investments are not contractible. Thus, bargaining only depends on equilibrium investments and does not vary with off-the-equilibrium path investments. One implication of this is that the payments to the worst-off types are not affected by actual investments. We suppose that the buyer and supplier first simultaneously make their investments and then bargaining takes place.

**First-best investments**

We first consider the planner’s problem of determining investments when the allocation rule is first-best. Denote the first-best allocation for a given realization of types by $Q_{FB}^i(v, c)$, where for $i \in \mathcal{N}$, $Q_{FB}^i(v, c)$ is equal to 1 if $v \geq c_i = \min_{j \in \mathcal{N}} c_j$ and equal to zero otherwise, and $Q_{FB}^B(v, c) = \sum_{i \in \mathcal{N}} Q_{FB}^i(v, c)$. Then, for a given realization of types, first-best welfare is

$$W_{FB}(v, c) \equiv \sum_{i \in \mathcal{N}} (v - c_i)Q_{FB}^i(v, c).$$

We let $\bar{e}$ denote first-best investments, which are a solution to the planner’s first-best investment problem, given by

$$\max_{e} \mathbb{E}_{v,c}[W_{FB}(v, c)] - \sum_{i \in \{B\} \cup \mathcal{N}} \Psi_i(e_i).$$

**Equilibrium investments**

Now consider the agents’ incentives to invest when incomplete information bargaining is such that the first-best is possible (see, e.g., Proposition 3 for conditions under which this is the case without symmetric bargaining weights). By the payoff equivalence theorem, it follows that, up to a constant, any incentive compatible mechanism generates the same interim and consequently the same ex ante expected utility for every agent. Thus, for the case considered here in which the first-best is possible, we can, without loss of generality, focus on expected utilities for the Vickrey-Clarke-Groves (VCG) mechanism. Given a type realization $(v, c)$, the VCG payment to supplier $i$ is

$$M_i(v, c) = W_{QFB}(v, c) + Q_{FB}^i(v, c)c_i - W_{QFB}(v, c_{-i}),$$

plus possibly a type-independent constant, implying that $i$’s payoff is

$$M_i(v, c) - Q_{FB}^i(v, c)c_i = W_{QFB}(v, c) - W_{QFB}(v, c_{-i}).$$

---

41This assumption also prevents the mechanism from using harsh punishments for deviations from any prescribed investment level.
plus possibly a constant. Likewise, the buyer’s payoff is

\[ Q_{FB}^B(v, c)v - M_B(v, c) = W_{Q_{FB}}(v, c) - W_{Q_{FB}}(v, c), \]

plus possibly a constant.

Taking expectations over \((v, c)\), and noticing that \(W_{Q_{FB}}(v, \bar{c}, c_{-i})\) is independent of supplier \(i\)'s type and its distribution and \(W_{Q_{FB}}(\bar{v}, c)\) is independent of the buyer’s type and its distribution, it follows that, at the investment stage, each supplier \(i\)'s problem, taking as given that the other agents choose investments \(e_{-i}\), is

\[
\max_{e_i} \mathbb{E}_{v, c | e_i, e_{-i}}[W_{FB}^B(v, c)] - \mathbb{E}_{v, c | e_i, e_{-i}}[W_{FB}^B(v, \bar{c}, c_{-i})] - \Psi_i(e_i),
\]

where the middle term is independent of \(e_i\). An analogous optimization problem applies to the buyer’s choice of \(e_B\). It then follows that the planner’s solution \(e\) is a Nash equilibrium if incomplete information bargaining permits the first-best. This proves the “if” part of the following proposition. The “only if” part is proved in the appendix. For the purposes of that part of the result, we say that the agents’ investment problem is smooth if distributions vary monotonically with investment throughout the interior of their supports and the investment cost functions are increasing and convex.

**Proposition 9.** The first-best investments are a Nash equilibrium of the simultaneous investment game if incomplete information bargaining is efficient; and incomplete information bargaining is efficient if first-best investments are a Nash equilibrium and the agents’ investment problem is smooth.

**Proof.** See Appendix [B].

As shown in Proposition [9], when incomplete information bargaining is efficient, the agents’ Nash equilibrium investment choices are first-best investments. In other words, efficient incomplete information bargaining implies efficient investments. Intuitively, given that the allocation rule is efficient and involves full trade, each agent is the residual claimant to the surplus that its investment generates. Anticipating that this will be the case once types are realized, each agent’s incentives are also aligned with the planner’s at the investment stage because each agent’s and the planner’s reward from investment are the same.

Corollary 2 allows us to also connect investment with countervailing power. As shown there, the equalization of bargaining weights that comes with countervailing power can lead bargaining to be efficient when it was not otherwise. This means that countervailing power can not only increase social surplus holding investment levels fixed, but can, by Proposition
also improve investments to the first-best level. Proposition [9] thus provides an additional channel—investments—through which countervailing power can increase social surplus.

Proposition [9] which shows that private information protects agents from hold-up\textsuperscript{42} contrasts the G-H-M literature, where hold-up occurs. Accordingly, the implications for institutional design differ sharply between incomplete information models in which the efficiency properties of bargaining are endogenous and complete information models that assume efficient bargaining. In the latter, the planner would aim to align, say, property rights with how the agents’ investments affect social surplus. In contrast, in incomplete information models, the planner would choose designs that render price formation efficient. Once price formation is efficient, efficient investments follow.

Hatfield et al. (2018) provide an equivalence result between efficient dominant-strategy mechanisms under incomplete information and efficient investments, which is obviously tightly related to Proposition [9]. Efficient dominant strategy mechanisms are equivalent to the Vickrey-Clarke-Groves (VCG) mechanism, and with independent private values, there is a well-known equivalence between Bayesian incentive compatibility and dominant strategy incentive compatibility (see e.g. Gershkov et al., 2013). In this way, Proposition [9] connects to the equivalence result of Hatfield et al. (2018) and to earlier work by Milgrom (1987) and Rogerson (1992).\textsuperscript{43} However, the no-deficit constraint in our setting implies that the VCG mechanism is not necessarily admissible with overlapping supports, which may preclude the first-best.

As is perhaps clear from the analysis above, the efficiency result of Proposition [9] continues to hold if instead of investments in cost reduction, each supplier can invest in the “quality” of its product. Specifically, suppose that when supplier $i$ makes investment $\theta_i \geq 0$ in the quality of its product, the buyer then has value $\theta_i v$ for supplier $i$’s product. In this setup, both the planner and supplier $i$ only value supplier $i$’s investment when the buyer trades with supplier $i$. Because the VCG mechanism gives supplier $i$ its social marginal product, accounting for the investment $\theta_i$, efficient investment levels continue to be a Nash equilibrium. This result contrasts with that of Che and Hausch (1999), who study a contracting setup in which investments by suppliers in cost reduction are efficient, but investments by suppliers that benefit the buyer need not be. Importantly, however, there is no incomplete information at the price-formation stage in their model. Our results do not hold if, for example, investment

\textsuperscript{42}In a setup where efficient bargaining is possible because of shared ownership (rather than the absence of any allocation-relevant private information), Schmitz (2002, p. 176) notes that “Intuitively, ... a party’s ex ante expected utility from an ex post efficient mechanism is (up to a constant) equal to the total expected surplus, so that each party is residual claimant on the margin from his or her point of view.”

\textsuperscript{43}Lauermann (2013) considers a dynamic search model and finds that it is easier/possible to converge to Walrasian efficiency with private information, but without private information, hold up prevents convergence to efficiency. These results are consistent with ours when one interprets search as investment.
generates externalities, e.g., if there are technology spillovers across suppliers or if investment increases the buyer’s value regardless of its trading partner. Che et al. (2017) consider the latter case and find that the buyer always wants to depart from ex post efficiency in order to boost ex ante investment by suppliers.

**Vertical integration and efficient investments**

Proposition 9 also allows us to analyze the effect of vertical integration on investment. With one supplier in the pre-integration market and overlapping supports, incomplete information bargaining is inefficient, implying that equilibrium investments are inefficient. But, by assumption, the allocation is efficient after vertical integration, which by Proposition 9 implies that investments are efficient after vertical integration. Thus, with overlapping supports, vertical integration promotes efficient investment insofar as there is an equilibrium with efficient investments after integration but not before. In contrast, with two or more suppliers and nonoverlapping supports, incomplete information bargaining is efficient for some bargaining weights, including symmetric ones, without vertical integration, which implies that investments are efficient without vertical integration. But following vertical integration, incomplete information bargaining is inefficient, and so investments are no longer efficient. Thus, with two or more suppliers and nonoverlapping supports, vertical integration disrupts efficient investment insofar as there is no equilibrium with efficient investments after integration whereas there was one before integration.

**Corollary 3.** With $n = 1$ and overlapping supports, vertical integration promotes efficient investment. In contrast, with $n \geq 2$ and nonoverlapping supports, vertical integration disrupts efficient investment if bargaining is efficient prior to vertical integration (which occurs, for example, with symmetric bargaining weights).

### 5.2 Heterogeneous outside options

The values of agents’ outside options are central for determining the division of social surplus in complete information bargaining models. We now briefly discuss how our model can be augmented or reinterpreted to account for similar features. As we show, there are two types of outside options that can vary across agents: the opportunity cost of participating in the mechanism and the opportunity cost of producing (or buying), which we address in turn. Some of the comparative statics with respect to these costs are the same as with complete information bargaining, while other aspects are novel relative to complete information models.
Fixed costs of participating in the mechanism

We first extend the model to allow the buyer and each supplier to have a positive outside option, denoted by $x_B \geq 0$ for the buyer and $x_i \geq 0$ for supplier $i$. These outside options are best thought of as fixed costs of participating in the mechanism because they have to be borne regardless of whether an agent trades. In this case, the price-formation mechanism with weights $w$ is the solution to

$$\max_{(Q,M)} \mathbb{E}_{v,c} \left[ W^w_{Q,M}(v,c) \right] \text{s.t. } \hat{u}_B(v;w,\eta_B) \geq x_B \text{ and for all } i \in \mathcal{N}, \hat{u}_i(v;w,\eta_i) \geq x_i,$$

over the set of incentive-compatible, individually-rational, no-deficit mechanisms. Similar to the case in which the value of the outside options was zero for all agents, the allocation rule is as defined in Lemma 1, but where $\beta^w$ is the largest $\beta \in [0, \max w]$ such that

$$\mathbb{E}_{v,c} \left[ \sum_{i \in \mathcal{N}} (\Phi(v) - \Gamma_i(c_i)) \cdot 1_{\Phi_{\beta}(v) \geq \Gamma_i(c_i) = \min_{j \in \mathcal{N}} \Gamma_j(c_j) \geq x_B + \sum_{i \in \mathcal{N}} x_i} \right] \geq x_B + \sum_{i \in \mathcal{N}} x_i, \quad (14)$$

if such a $\beta$ exists (if no such $\beta$ exists, then the constraints cannot be met). If (14) holds strictly for $\beta = 1/ \max w$, then the price-formation mechanism allocates the surplus beyond the outside options to the agent or agents with the maximum bargaining weights according to shares $\eta$.

Consider the case of symmetric suppliers in this setup. As the number of suppliers increases, the range of outside options that can be accommodated increases. As the suppliers’ outside option increases, the expected social surplus decreases—the need to generate revenue for the suppliers distorts the overall market outcome—and eventually the suppliers’ payoffs exceed that of the buyer, even if the buyer has all the bargaining power. Further, if the suppliers’ outside option is sufficiently large, then the buyer is better off when the number of suppliers is reduced below the maximum number sustainable in the market.

Production-relevant outside options

Alternatively, one can think of outside options as affecting a supplier’s cost of producing or as the buyer’s best alternative to procuring the good. Typically, one would expect these to be more sizeable than the costs of participating in the mechanism. To allow for heterogeneity in these production-relevant outside options, we now relax the assumption that all suppliers’ cost distributions have the identical support $[c, \bar{c}]$ and assume instead that, with a commonly known outside option of value $y_i \geq 0$, the support of supplier $i$’s cost distribution is $[c_i, \bar{c}_i]$ with $c_i = c + y_i$ and $\bar{c}_i = \bar{c} + y_i$. If $G_i(c)$ is $i$’s cost distribution without the outside option,
then given outside option \( y_i \), its cost distribution is

\[
G_i^o(c) = G_i(c - y_i),
\]

with density \( g_i^o(c) = g_i(c - y_i) \) and support \( [c_i, \bar{c}_i] \). In other words, increasing a supplier’s outside option shifts its distribution to the right without changing its shape. Likewise, given outside option \( y_B \geq 0 \), the distribution of the buyer’s value \( v \) is

\[
F_o(v) = F(v + y_B)
\]

with density \( f_o(v) = f(v + y_B) \) and support \( [\underline{v}, \overline{v}] - y_B \).

Increasing the value of an agent’s outside option has two effects. First, it worsens its distribution in the sense that for \( y_i > 0 \) and \( y_B > 0 \), we have \( G_i^o(c) \leq G_i(c) \) for all \( c \) and \( F^o(v) \geq F(v) \) for all \( v \). Hence, under the first-best, an agent is less likely to trade the larger is the value of its outside option. While this effect differs from what one would usually obtain in complete information models, it is an immediate implication of the “worsening” of the agent’s distribution.

The second effect is less immediate and partly but not completely offsets the first under the assumption that hazard rates are monotone, that is, assuming that \( G_i(c)/g_i(c) \) is increasing in \( c \) and \((1 - F(v))/f(v)\) is decreasing in \( v \). To see this, let us focus on supplier \( i \). The arguments for the buyer (and of course all other suppliers) are analogous. We denote the weighted virtual cost of supplier \( i \) when it has outside option \( y_i \) by

\[
\Gamma_i^o(a,c) \equiv c + (1 - a) \frac{G_i(c - y_i)}{g_i(c - y_i)} = \Gamma_i(a,c) + y < \Gamma_i(a,c),
\]

where the inequality holds for all \( a < 1 \) because the monotone hazard rate assumption implies that \( \Gamma_i^o > 1 \) for all \( a < 1 \). This in turn has two, somewhat subtle implications. Let \( z \) be the threshold for supplier \( i \) to trade when its outside option is zero, i.e., keeping \( z \) fixed, \( i \) trades if and only if \( \Gamma_i(a,c) \leq z \). (Note that \( z \) will be the minimum of the buyer’s weighted virtual value and the smallest weighted virtual cost of \( i \)'s competitors, but this does not matter for the argument that follows.) Assuming that \( a < 1 \) and \( y_i < \bar{c} - c_i \), which implies that \( c_i < \bar{c} \), it follows that there are costs \( c \in [c_i, \bar{c}] \) and thresholds \( z \) such that supplier \( i \) trades when it has the outside option and not without it, that is,

\[
\Gamma_i^o(a,c) < z < \Gamma_i(a,c).
\]

This reflects the reasonably well-known result that optimal mechanisms tend to discriminate in favour of weaker agents \cite{McAfee and McMillan 1987}, which in this case is the agent with the positive outside option. It also resonates with intuition from complete information models: keeping costs fixed, the agent with the better outside option is treated more favor-
ably, indeed, it is evaluated according to a smaller weighted virtual cost. However, from an ex ante perspective, the larger is the value of the outside option, the less likely is the agent to trade. To see this, consider a fixed realization of $z$. (The distribution of these thresholds is not be affected by $i$’s outside option and hence our argument extends directly once one integrates over $z$ and its density.) Given $y_i$, supplier $i$ trades if and only if its cost $c$ is below $r(y)$ satisfying $\Gamma_{i,a}(r(y)) = z$. Using (15), this is equivalent to

$$\Gamma_{i,a}(r(y) - y) + y = z,$$

which in turn is equivalent to $r(y) = \Gamma_{i,a}^{-1}(z - y) + y$, whose derivative for $a < 1$ satisfies

$$0 < r'(y) = -\frac{1}{\Gamma_{i,a}'(\Gamma_{i,a}^{-1}(z - y))} + 1 < 1,$$

where the inequalities follow because $\Gamma_{i,a}' > 1$. This implies that, for a fixed $z$, the probability that $i$ trades decreases in $y$. To see this, notice that this probability is

$$G_{i,a}(r(y)) = G_i(r(y) - y),$$

whose derivative with respect to $y$ is $g_i(r(y) - y)(r'(y) - 1) < 0$. In words, although the threshold $r(y)$ increases in $y$, it does so with a slope that is less than 1, which implies that the probability that supplier $i$ trades decreases in $y$. This effect is, of course, not present in complete information models, which in a sense take an ex post perspective by looking at outcomes realization by realization. While improving the outside option $y_i$ improves supplier $i$’s payoff after its value or cost has been realized, supplier $i$’s ex ante expected payoff decreases in $y_i$. Moreover, because an increase in $y_i$ worsens supplier $i$’s distribution, the revenue constraint becomes (weakly) tighter, implying a decrease in $\beta^\alpha$, which further reduces supplier $i$’s expected payoff.

### 5.3 Bargaining externalities

To allow for and investigate bargaining externalities, we now return to the model without investment and with outside options of zero, but generalize it to allow the buyer to have preferences over suppliers and to have demand for $D \in \{1, 2, \ldots\}$ objects. To this end, we let $\theta = (\theta_1, \ldots, \theta_n)$ be a commonly known vector of taste parameters of the buyer, with the meaning that the value to the buyer of trade with supplier $i$ when the buyer’s type is $v$ is $\theta_i v$. Thus, under (ex post) efficiency, trade should occur between the buyer and supplier $i$ if and only if $\theta_i v - c_i$ is positive and among the $D$ highest values of $(\theta_j v - c_j)_{j \in \mathcal{N}}$. The problem
is trivial if \( \max_{i \in \mathcal{N}} \theta_i v \leq \zeta \) because then it is never ex post efficient to have trade with any supplier, so assume that \( \max_{i \in \mathcal{N}} \theta_i v > \zeta \).

This setup encompasses (i) differentiated products by letting the supplier-specific taste parameters differ; (ii) a one-buyer version of the Shapley and Shubik (1972) model by setting \( D = 1 \); and (iii) a version of the Shapley-Shubik model in which the buyer has demand for multiple products of the suppliers by setting \( D > 1 \). For an extension of the one-to-many setup that encompasses additional models, see Appendix D.

We define the virtual surplus \( \Lambda^w,\theta(v, c_i) \) associated with trade between the buyer and supplier \( i \), accounting for the agents’ bargaining weights \( w \) and the buyer’s preferences \( \theta \), with \( \beta^w,\theta \) defined analogously to before as

\[
\Lambda^w,\theta(v, c_i) \equiv \theta_i \Phi_{v_B \beta^w,\theta}(v) - \Gamma_{v_B \beta^w,\theta}(c_i).
\]

Let \( \Lambda^w(v, c) \equiv (\Lambda^w,\theta(v, c_i))_{i \in \mathcal{N}} \) and denote by \( \Lambda^w(v, c)(D) \) the \( D \)-th highest element of \( \Lambda^w(v, c) \). As before, in order to save notation, we ignore ties.

**Lemma 2.** In the generalized setup with buyer preferences \( \theta \), the price-formation mechanism with weights \( w \) has the allocation rule for \( i \in \mathcal{N} \),

\[
Q^w,\theta_i(v, c_i) \equiv 1 \text{ if } \Lambda^w,\theta(v, c_i) \geq \max\{0, \Lambda^w(v, c)(D)\},
\]

and otherwise \( Q^w,\theta_i(v, c_i) \equiv 0 \) while for the buyer, \( Q^w_B(v, c) \equiv \sum_{i \in \mathcal{N}} Q^w_i(v, c) \).

**Proof.** See Appendix B.

We can now use this generalized setup to analyze bargaining externalities between suppliers. If \( D < n \), then one effect of an increase in \( \theta_i \) is that agents other than \( i \) are less likely to be among the at-most \( D \) agents that trade. In contrast, if \( D \geq n \) and \( \beta^w,\theta < 1/\max w \), then the probability that supplier \( i \) trades, \( \Pr(\theta_i \Phi_{v_B \beta^w,\theta}(v) \geq \Gamma_{v_B \beta^w,\theta}(c_i)) \), does not depend on the preference parameters of the other suppliers except through their effect on \( \beta^w,\theta \). Because an increase in a rival supplier’s preference parameter causes an increase in \( \beta^w,\theta \), it increases the probability of trade and so benefits the supplier. Thus, we have the following result:

**Proposition 10.** In the generalized setup with bargaining weights \( w \) and buyer preferences \( \theta \), if \( D \geq n \) and \( \beta^w,\theta < 1/\max w \), then an increase in the preference parameter for one supplier increases the payoffs for all suppliers.

The result of Proposition 10 no longer holds when \( D < n \), as shown in the example of Appendix E. In that example, even though an increase in \( \theta_i \) increases \( \beta^w,\theta \), which benefits rivals, it also reduces the probability that rivals are among the set of at-most \( D \) suppliers.
that trade. In contrast, when $D \geq n$, the example shows the positive externalities associated with an increase in $\theta_i$ as described in Proposition 10.

6 Related literature

As noted, while intuitive and appealing to many, the concept of countervailing power has been the subject of controversy ever since it was introduced by Galbraith (1952); see, for example, the debate between Galbraith and Stigler (Galbraith 1954; Stigler 1954) and the overview by Snyder (2008). A considerable part of the skepticism that the idea of countervailing power encounters stems from the fact that it is difficult to conceptualize in a basic economic model of one-shot, static exchange\textsuperscript{44}. We provide an incomplete information bargaining model in which the possibility of countervailing power arises naturally because of the inherent tradeoff between social surplus and rent extraction: with independent private values, neither the mechanism that is optimal for buyer nor the one that is optimal for the suppliers (or a supplier) is efficient in general, which opens the scope for increasing social surplus by making bargaining powers more equal.

A key observation of the present paper is the importance of distinguishing between an agent’s productive power and its bargaining power. Considering horizontal mergers in a procurement setup that is otherwise similar to the one here and keeping bargaining powers fixed before and after mergers, Loertscher and Marx (2019) find that mergers among symmetric suppliers never increase social surplus. While a merger eliminates a competing bid for the merged entity and improves its cost distribution, and hence its productive power, their analysis largely leaves bargaining powers unchanged before and after a merger.

The incomplete information bargaining model in this paper offers novel and economically relevant insights. For example, it implies that there is no basis for the presumption that vertical integration increases social surplus because vertical integration may make bargaining inefficient when it was efficient without integration by essentially creating a Myerson-Satterthwaite problem when there was none\textsuperscript{45}. Our model thus has the property that vertical integration can be detrimental to social surplus without relying on complete information bargaining, which, for example, Judge Leon found unconvincing in the AT&T-Time-Warner

\textsuperscript{44}In settings with non-contractible investments preceding transactions, or similar two-stage games in the tradition of Grossman and Hart (1986) and Hart and Moore (1990), there is, of course, an element of countervailing power insofar as “property rights” or bargaining that align with the investment incentives tend improve social surplus. We provide an extended discussion of this strand of literature below.

\textsuperscript{45}For an overview of the literature on the competitive effects of vertical integration, see Riordan and Salop (1995). As described there, the literature has taken the view that most vertical mergers lead to some efficiencies.
Consistent with our results in Section 4.2, the literature on vertical integration and foreclosure also notes that a vertical merger that eliminates internal frictions may create or exacerbate external ones for the case where buyers are competing downstream intermediaries. Ordover et al. (1990) and Salinger (1988) show that vertical integration leads to an increase in rivals’ (linear) prices and Hart and Tirole (1990) provide a similar insight in the context of secret contracting, without restriction to linear tariffs. Nocke and Rey (2018) and Rey and Vergé (2019), extend the latter insight to multiple strategic suppliers for Cournot and Bertrand downstream competition. Allain et al. (2016) show that, while vertical integration solves hold-up problems for the merging parties, it may also create or exacerbate problems for rivals.

The incomplete information bargaining approach also has implications for two-stage models in which investments precede bargaining. These have been at the center of attention in incomplete-contracting models in the tradition of Grossman and Hart (1986) and Hart and Moore (1990), where bargaining, which is assumed to be efficient and occurs under complete information, creates a hold-up problem and induces inefficient levels of investment. Under incomplete information, there is also a tight connection between the efficiency of bargaining and the equilibrium levels of investment. The predictions, however, could hardly differ more starkly from those in complete information models because, with incomplete information bargaining, investments are efficient if and only if bargaining is efficient. Moreover, in the wake of the Dow-DuPont merger decision, there has been an upsurge of interest in industrial organization relating to market structure and the incentives to invest (see, e.g., Federico et al., 2017, 2018; Jullien and Lefouili, 2018; Loertscher and Marx, 2019), onto

---

46In the U.S. government’s attempt to enjoin the vertical merger between AT&T and Time Warner, Judge Richard Leon did not embrace the complete information bargaining model put forward by the Government, reaching the “conclusion that the Government has failed to provide sufficient evidentiary support to show the Nash bargaining theory accurately reflects post-merger affiliate negotiations or the proffered bargaining model in this case.” Further, after likening the Nash bargaining model to a Rube Goldberg contraption, Judge Leon said, “But in fairness to Mr. Goldberg, at least his contraptions would normally move a pea from one side of a room to another” (U.S. v. AT&T Inc., et al., 290 F.Supp.3d 1, D.C. 2018, pp. 19, 32).

47Nocke and Thanassoulis (2014) provide model within the paradigm of efficient, complete information bargaining in which there is scope for countervailing power because bargaining power can mitigate frictions due to credit constraints.

48The tight connection between incentives for efficient investment and efficiency in incomplete information models has its roots in the seminal works of Vickrey (1961), Clarke (1971), and Groves (1973) and the subsequent uniqueness results of Green and Laffont (1977) and Holmström (1979). Essentially, dominant strategy incentive compatibility under incomplete information requires each agent to be a price taker, and efficiency then further requires this price to be equal to the agent’s social marginal product (or cost). As demonstrated by Milgrom (1987), Rogerson (1992), Hatfield et al. (2018), and Loertscher and Riordan (2019), this is precisely the set of conditions that have to be satisfied for incentives for investment to be aligned with efficiency.
which our paper—in particular, the results pertaining to mergers and vertical integration and investment—sheds new light as well. For example, with investment countervailing power that renders efficient bargaining possible has the additional benefit of making first-best investments an equilibrium outcome, which is not the case if bargaining is not efficient.

There has also been a recent upsurge of interest in bargaining (see, for example, Larsen, 2020; Backus et al., 2020; 2019; Zhang et al., 2019; Decarolis and Rovigatti, 2020), and buyer power (see, for example, Snyder, 1996; Nocke and Thanassoulis, 2014; Caprice and Rey, 2015; Loertscher and Marx, 2019). Bargaining has also come to the forefront of the empirical IO literature, in particular in analyses of bundling and vertical integration such as Crawford and Yurukoglu (2012) and Crawford et al. (2018). Collard-Wexler et al. (2019) and Rey and Vergé (2019) provide recent theoretical foundations for the widely used Nash-in-Nash bargaining model. Ho and Lee (2017) apply this framework to the question of countervailing power by insurers when negotiating with hospitals and find evidence that consolidation among insurers improves their bargaining position vis-à-vis hospitals. Our paper contributes to this literature by showing, among other things, that in incomplete information models, bargaining breakdown occurs on the equilibrium path and that the probability of breakdown can, under suitable assumptions, be used to estimate distributions. Ausubel et al. (2002) explicitly account for inefficiencies in bargaining and focus on the second-best mechanisms introduced by Myerson and Satterthwaite (1983), as do we; however, they focus on the robustness of the Bayesian mechanism design setting in two-person bargaining, which appears not to be a central concern for applied work, given the frequent reliance on models based on Nash bargaining, in which agents literally know each other’s types.

Given the skepticism of George Stigler towards the notion of countervailing power and our incomplete information approach to it, it is not without irony that he provided early and forceful arguments that private information held by economic agents is a major obstacle to achieving efficient outcomes, noting that “important aspects of economic organization take on a new meaning when they are considered from the viewpoint of the search for information” (Stigler, 1961, p. 213). While Stigler emphasized price dispersion and the problem of uncertainty about price cuts faced by cartels (Stigler, 1964), the relevance of private information in connection to prices applies, of course, generally. Viewed from this angle, we use the Myersonian mechanism design machinery (Myerson, 1981) to elicit—search for, as it were—agents’ private information and determine prices. Indeed, our framework builds on the bilateral trade model of Myerson and Satterthwaite (1983), augmented by

49While the empirical literature examining multilateral bargaining focuses on fixed quantities or linear tariffs, Rey and Vergé (2019) allow for non-linear tariffs, take into account the impact of these tariffs on downstream competition (placing it outside the approach of Collard-Wexler et al. (2019)), and provide a micro-foundation for Nash-in-Nash.
bargaining weights and multiple suppliers. Thereby, it combines elements of Myerson and Satterthwaite (1983), Williams (1987), and Gresik and Satterthwaite (1989). Specifically, our procurement model allows for multiple suppliers without imposing restrictions on the supports of the buyer’s value and the suppliers’ costs other than assuming that all cost distributions have the same support.\footnote{While Gresik and Satterthwaite (1989) also allow for multiple buyers, they restrict attention to identical cost distributions. In that regard, our setup thus shares similarities with the optimal auction setting of Myerson (1981), with the important difference that our setup has two-sided private information.}

We generalize Williams’ approach of maximizing an objective that assigns differential weights in a bilateral trade problem by allowing for multiple agents. In light of the quote from New Palgrave Dictionary in the introductory paragraph, our paper reinterprets Myerson and Satterthwaite (1983) as a bilateral monopoly problem, extends it to allow for multiple agents on one side of the market and bargaining weights, shows that it is tractable and has all the required features.\footnote{For experimental results consistent with the incomplete information bargaining, see Valley et al. (2002, Fig. 3.A). See Larsen (2020) on the first-best and second-best frontiers for wholesale used cars.}

In particular, inherent to the independent private values setting is a tradeoff between rent extraction and social surplus, which is at the heart of industrial organization. Privacy of information provides agents with protection against hold-up. This applies, as discussed, when the agents invest, but it also means that first-degree price discrimination is not possible because eliciting information about types comes at a cost.\footnote{Appendix F provides additional discussion of the properties of the independent private values paradigm.}

### 7 Conclusions

We analyze a procurement setup with incomplete information that pertains to both sides of the market in which price formation and its social surplus properties are endogenous and depend, among other things, on the bargaining power of the buyer and the suppliers. Social surplus increasing countervailing power and socially harmful vertical integration arise naturally in this setting. We also examine the relation between the efficiency of incomplete information bargaining and the incentives to invest, which differs fundamentally from what obtains in complete information models that are based on the assumption that efficient trade is always possible, and we illustrate the effects of bargaining externalities.

Our paper shows that an economic agent’s strength or weakness has two dimensions that are, conceptually, independent. The first one, which may be thought of as the agent’s productive strength or power, refers to the agent’s productivity. Is the agent likely to have a high value if it is a buyer or a low cost if it is a supplier? The second dimension captures the agent’s bargaining power, that is, its ability (or inability) to affect bargaining in its favour.
For example, a buyer who has all the bargaining power facing a single supplier makes higher or lower take-it-or-leave-it offers depending on the realization of its value, and on average these offers will be higher if the buyer’s distribution is stronger, say, in the sense of stochastic dominance. What is indicative of the relative bargaining powers is then not so much the level of prices but rather the price-formation process itself. For example, in a bilateral trade setting, if the buyer (supplier) always makes the price offer, then one would conclude that the buyer (supplier) has all the bargaining power, indicating that there is scope for countervailing power. In contrast, if the buyer and supplier participate in a $k$-double auction with $k = 1/2$, then this may be indicative of equal bargaining powers, suggesting that there is no scope for welfare increasing countervailing power.

Avenues for future research are many. For example, one could augment the setup to have multiple buyers and multiple suppliers, which may give rise to a raising rivals’ costs effect of vertical integration. More fundamentally, developing a better understanding of what determines bargaining power would add considerable value. The distinction between productive strength and bargaining power brought to light in the present paper may prove useful in that regard.
A Appendix: Mechanism design foundations

In this appendix, we first define and develop the mechanism design concepts relevant for our analysis (Appendix A.1) and then apply these concepts to derive the Myerson-Satterthwaite impossibility result (Appendix A.2).

A.1 Concepts and derivations

For ease of exposition, in this appendix we assume that \( n = 1 \). The extension to \( n > 1 \) is straightforward.

Take as given a direct mechanism \( \langle Q, M_B, M_S \rangle \) mapping buyer and supplier reports to a probability of trade and payments, \( Q : [v, \bar{v}] \times [c, \bar{c}] \to [0, 1] \) and \( M_B, M_S : [v, \bar{v}] \times [c, \bar{c}] \to \mathbb{R} \), where, given reports \( v \) and \( c \), \( Q(v, c) \in [0, 1] \) is the probability with which the supplier trades with the buyer, \( M_B(v, c) \) is the payment from the buyer to the mechanism, and \( M_S(v, c) \) is the payment from the mechanism to the supplier. By the Revelation Principle, the focus on direct mechanisms is without loss of generality.

Let \( \hat{q}_B(z) \) be the buyer’s expected quantity if it reports \( z \) and the supplier reports truthfully, and let \( \hat{m}_B(z) \) be the buyer’s expected payment if it reports \( z \) and the supplier reports truthfully:

\[
\hat{q}_B(z) = \mathbb{E}_c[Q(z, c)] \quad \text{and} \quad \hat{m}_B(z) = \mathbb{E}_c[M_B(z, c)].
\]

Define \( \hat{q}_S \) and \( \hat{m}_S \) analogously, where \( \hat{m}_S \) is the expected payment to the supplier. Because we assume independent draws, for \( i \in \{B, S\} \), \( \hat{q}_i(z) \) and \( \hat{m}_i(z) \) depend only on the report \( z \) and not on the reporting agent’s true type. The expected payoff of a buyer with type \( v \) that reports \( z \) is then \( \hat{q}_B(z)v - \hat{m}_B(z) \), and the expected payoff of a supplier with type \( c \) that reports \( z \) is \( \hat{m}_S(z) - \hat{q}_S(z)c \).

Key constraints

The mechanism is \emph{incentive compatible} for the buyer if for all \( v, z \in [v, \bar{v}] \),

\[
\hat{u}_B(v) \equiv \hat{q}_B(v)v - \hat{m}_B(v) \geq \hat{q}_B(z)v - \hat{m}_B(z), \quad (16)
\]

and is \emph{incentive compatible} for the supplier if for all \( c, z \in [c, \bar{c}] \),

\[
\hat{u}_S(c) \equiv \hat{m}_S(c) - \hat{q}_S(c)c \geq \hat{m}_S(z) - \hat{q}_S(z)c. \quad (17)
\]
Individual rationality is satisfied for the buyer if for all \( v \in [\underline{v}, \overline{v}] \), \( \hat{u}_B(v) \geq 0 \), and for the supplier if for all \( c \in [\underline{c}, \overline{c}] \), \( \hat{u}_S(c) \geq 0 \). The mechanism satisfies the no-deficit condition if
\[
\mathbb{E}_{v,c}[M_B(v,c) - M_S(v,c)] \geq 0.
\]

Interim expected payoffs

Standard arguments (see, e.g., Krishna, 2002, Chapter 5.1) proceed as follows:

Focusing on the buyers, incentive compatibility implies that
\[
\hat{u}_B(v) = \max_{z \in [\underline{v}, \overline{v}]} \{ \hat{q}_B(z) v - \hat{m}_B(z) \},
\]
i.e., \( \hat{u}_B \) is a maximum of a family of affine functions, which implies that \( \hat{u}_B \) is convex and so absolutely continuous and differentiable almost everywhere in the interior of its domain. In addition, incentive compatibility implies that
\[
\hat{u}_B(z) \geq \hat{q}_B(v) z - \hat{m}_B(v) = \hat{u}_B(v) + \hat{q}_B(v)(z - v),
\]
which for \( \varepsilon > 0 \) implies
\[
\frac{\hat{u}_B(v + \varepsilon) - \hat{u}_B(v)}{\varepsilon} \geq \hat{q}_B(v)
\]
and for \( \varepsilon < 0 \) implies
\[
\frac{\hat{u}_B(v + \varepsilon) - \hat{u}_B(v)}{\varepsilon} \leq \hat{q}_B(v),
\]
so taking the limit as \( \varepsilon \) goes to zero, at every point \( v \) where \( \hat{u}_B \) is differentiable, \( \hat{u}_B'(v) = \hat{q}_B(v) \).

Because \( \hat{u}_B \) is convex, this implies that \( \hat{q}_B(v) \) is nondecreasing. Because every absolutely continuous function is the definite integral of its derivative,
\[
\hat{u}_B(v) = \hat{u}_B(v_1) + \int_{v_1}^{v} \hat{q}_B(t)dt,
\]
which implies that, up to an additive constant, a buyer’s expected payoff in an incentive-compatible direct mechanism depends only on the allocation rule. By an analogous argument, \( \hat{u}_S'(c) = -\hat{q}_S(c) \), \( \hat{q}_S(c) \) is nonincreasing, and
\[
\hat{u}_S(c) = \hat{u}_S(\overline{c}) + \int_{\underline{c}}^{c} \hat{q}_S(t)dt.
\]

---

53 A function \( h : [\underline{v}, \overline{v}] \to \mathbb{R} \) is absolutely continuous if for all \( \varepsilon > 0 \) there exists \( \delta > 0 \) such that whenever a finite sequence of pairwise disjoint sub-intervals \( (v_k, v'_k) \) of \( [\underline{v}, \overline{v}] \) satisfies \( \sum_k (v'_k - v_k) < \delta \), then \( \sum_k |h(v'_k) - h(v_k)| < \varepsilon \). One can show that absolute continuity on compact interval \([a, b]\) implies that \( h \) has a derivative \( h' \) almost everywhere, the derivative is Lebesgue integrable, and that \( h(x) = h(a) + \int_{a}^{x} h'(t)dt \) for all \( x \in [a, b] \).
Mechanism budget surplus

Using the definitions of $\hat{u}_B$ and $\hat{u}_S$ in (16) and (17), we can rewrite these as

$$\hat{m}_B(v) = \hat{q}_B(v)v - \int_v^u \hat{q}_B(t)dt - \hat{u}_B(v)$$

and

$$\hat{m}_S(c) = \hat{q}_S(c)c + \int_c^\infty \hat{q}_S(t)dt + \hat{u}_S(\tau).$$

The expected payment by the buyer is then

$$\mathbb{E}_v [\hat{m}_B(v)] = \int_v^\infty \hat{m}_B(v)f(v)dv$$

where the first equality uses the definition of the expectation, the second uses (18), the third switches the order of integration, the fourth integrates, the fifth collects terms, the sixth uses the definition of the virtual value $\Phi$, and the last equality uses the definition of the expectation. Similarly, using (19), the expected payment to the supplier is

$$\mathbb{E}_c [\hat{m}_S(c)] = \int_c^\infty \hat{m}_S(c)g(c)dc = \mathbb{E}_c [\hat{q}_S(c)\Gamma(c)] + \hat{u}_S(\tau).$$

Thus, imposing $Q_B(v, c) = Q_S(v, c)$, we have the result that in any incentive-compatible, interim individually-rational direct mechanism $\langle Q, M_B, M_S \rangle$, the mechanism’s expected budget surplus is

$$\mathbb{E}_{v,c} [(\Phi(v) - \Gamma(c)) Q(v, c)] - \hat{u}_B(v) - \hat{u}_S(\tau).$$

As mentioned, it is straightforward to extend these results to the case of $n > 1$. 

46
A.2 Myerson-Satterthwaite impossibility result

For the purpose of making the paper self-contained, we provide a statement and proof of the impossibility theorem of Myerson and Satterthwaite (1983). Under the assumption of independent private values and the assumption that $v < c$, Myerson and Satterthwaite (1983) show that there is no mechanism satisfying incentive compatibility and individual rationality that allocates ex post efficiently and that does not run a deficit. Their result depends on $v < c$ because, without this assumption, ex post efficiency subject to incentive compatibility and individual rationality can easily be achieved without running a deficit. For example, the posted price mechanism that has the buyer pay $p = \frac{v + c}{2}$ to the supplier achieves this.

By now, the proof of this result can be provided in a couple of lines (see, e.g, Krishna, 2002). Consider the dominant strategy implementation in which the buyer pays $p_B = \max\{c, v\}$ and the supplier receives $p_S = \min\{v, \bar{c}\}$ whenever there is trade, and no payments are made otherwise. Notice that $\hat{u}_B(v) = 0 = \hat{u}_S(\bar{c})$. Thus, the individual rationality constraints are satisfied. Further, notice that $p_B - p_S \leq 0$, with a strict inequality for almost all type realizations. This implies that the mechanism runs a deficit in expectation. By the payoff equivalence theorem, any other ex post efficient mechanism satisfying incentive compatibility and individual rationality will run a deficit of at least that size (and a larger one if one or both of the individual rationality constraints are slack).

To see how this impossibility result rests on the assumption $v < c$, assume to the contrary that $v \geq c$. Then the mechanism described above continues to satisfy incentive compatibility and individual rationality, but for all type realizations $p_B = v \geq \bar{c} = p_S$, which implies that the mechanism does not run a deficit.
B Appendix: Proofs

Proof of Lemma 1. As mentioned in the text, \( Q_\rho \) maximizes \((6)\) pointwise given \( \rho \). Given that \( \rho > 0 \), we can write \( \sum \) as

\[
E_{w,c} \left[ \sum_{i \in \mathcal{N}} [w_B(v - \Phi(v)) + w_i(\Gamma_i(c_i) - c_i) + \rho(\Phi(v) - \Gamma_i(c_i))] Q_i(v, c) \right]
\]

which is maximized pointwise by having \( Q_{i,\rho}(v, c) = 1 \) if and only if \( \Phi_{w_B/\rho}(v) \geq \Gamma_{i,w_i/\rho}(c_i) \), and zero otherwise. The result then follows by making the substitution \( \beta^*(w) = 1/\rho \). \( \blacksquare \)

Proof of Proposition 2. Let \( \mathcal{M} \) be the set of incentive-compatible, individually-rational, no-deficit mechanisms. Let \( \langle Q^w, M^{w, \eta} \rangle \in \mathcal{M} \) denote the price-formation mechanism with weights \( w \) and shares \( \eta \), with associated expected payoff vector \( u(w, \eta) \). Thus, the maximized value of expected weighted welfare over all mechanisms in \( \mathcal{M} \) is \( \sum_{i \in \{B\} \cup \mathcal{N}} w_i u_i(w, \eta) \).

We first show that the expected payoffs from \( \langle Q^w, M^{w, \eta} \rangle \) are Pareto undominated among the expected payoffs for any mechanism in \( \mathcal{M} \). Proceeding by contradiction, suppose that \( u(w, \eta) \) is Pareto dominated by expected payoff vector \( \tilde{u} \) associated with a mechanism \( \langle \tilde{Q}, \tilde{M} \rangle \in \mathcal{M} \), i.e., \( \tilde{u}_i \geq u_i(w, \eta) \) for all \( i \in \{B\} \cup \mathcal{N} \) and there exists \( \ell \in \{B\} \cup \mathcal{N} \) such that \( \tilde{u}_\ell > u_\ell(w, \eta) \). If there exists \( i \in \{B\} \cup \mathcal{N} \) such that \( \tilde{u}_i > u_i(w, \eta) \) and \( w_i > 0 \), then \( \sum_{i \in \{B\} \cup \mathcal{N}} w_i u_i > \sum_{i \in \{B\} \cup \mathcal{N}} w_i u_i(w, \eta) \), implying that \( \langle Q^w, M^{w, \eta} \rangle \) does not maximize expected weighted welfare over mechanisms in \( \mathcal{M} \), which is a contradiction. So, for all \( i \in \{B\} \cup \mathcal{N} \) such that \( \tilde{u}_i > u_i(w, \eta) \), we have \( w_i = 0 \). It follows that \( \sum_{i \in \{B\} \cup \mathcal{N}} w_i \tilde{u}_i = \sum_{i \in \{B\} \cup \mathcal{N}} w_i u_i(w, \eta) \), which says that \( \langle \tilde{Q}, \tilde{M} \rangle \) maximizes expected weighted welfare. By the uniqueness of the allocation rule identified in Lemma 1, we have \( \tilde{Q} = Q^w \). Thus, using the payoff equivalence theorem, the difference \( \tilde{u}_\ell - u_\ell(w, \eta) \) reflects an increase in the interim expected payment to agent \( \ell \)'s worst-off type. It follows that there exists a mechanism in \( \mathcal{M} \).
that has allocation rule $Q^w$ and payment rule based on $\tilde{M}$, but that redirects agent $\ell$’s fixed payment to an agent with positive bargaining weight, that has greater expected weighted welfare than $\langle Q^w, M^w, n \rangle$, which is a contradiction. This concludes the first part of the proof.

We now turn to the proof that any Pareto undominated payoff vector can be achieved using $\langle Q^w, M^w, n \rangle$ with appropriately chosen weights and shares. Let $\tilde{u}$ be a Pareto undominated payoff profile associated with $\langle \tilde{Q}, \tilde{M} \rangle \in \mathcal{M}$. By the assumption of Pareto undominatedness, $\tilde{u}_B$ solves

$$\max_{\langle Q, M \rangle \in \mathcal{M}} u_B \text{ s.t. } u_1 \geq \tilde{u}_1, ..., u_n \geq \tilde{u}_n.$$ 

Using incentive compatibility and individual rationality, the above problem can be recast as choosing $Q$, $\tilde{u}_B(v) \geq 0$, and $\tilde{u}_i(\tau) \geq 0$ for all $i \in N$, subject to no deficit and the suppliers’ payoff constraints, which has associated Lagrangian

$$\mathcal{L} = \mathbb{E}_{v,c} \left[ \sum_{i \in N} \left[ v - \Phi(v) + \rho(\Phi(v) - \Gamma_i(c_i)) + \mu_i(\Gamma_i(c_i) - c_i) \right] Q_i(v, c) \right] + (1 - \rho)\tilde{u}_B(v) + \sum_{i \in N} (\mu_i - \rho)\tilde{u}_i(\tau) - \sum_{i \in N} \mu_i\tilde{u}_i,$$

where $\rho \geq 0$ is the multiplier on the no-deficit constraint and $\mu_i \geq 0$ is the multiplier on the constraint that $u_i \geq \tilde{u}_i$. If $\rho < 1$, then we maximize $\mathcal{L}$ by increasing $\tilde{u}_B(v)$ unboundedly, in violation of the no-deficit constraint, so $\rho \geq 1$.

Maximizing $\mathcal{L}$ pointwise, $\tilde{Q}_i$ is defined by

$$\tilde{Q}_i(v, c) = \begin{cases} 1 & \text{if } \Phi^1(v) \geq \Gamma_{i,v}(c_i) = \min_{j \in N} \frac{\Gamma_{j,v}}{\rho}(c_j), \\ 0 & \text{otherwise}, \end{cases}$$

where $\rho$ is the smallest value greater than or equal to 1 such that the no-deficit constraint is satisfied under allocation rule $\tilde{Q}_i(v, c)$. It then follows that

$$\tilde{u}_i(\tau) = \tilde{u}_i - \mathbb{E}_{v,c} \left[ (\Gamma_i(c_i) - c_i)\tilde{Q}_i(v, c) \right]$$

and

$$\tilde{u}_B(v) = \mathbb{E}_{v,c} \left[ \sum_{i \in N} (\Phi(v) - \Gamma_i(c_i))\tilde{Q}_i(v, c) \right] - \sum_{i \in N} \tilde{u}_i(\tau).$$

**Case 1:** Suppose that $\mathbb{E}_{v,c} \left[ \sum_{i \in N} (v - \Phi(v))\tilde{Q}_i(v, c) \right] < \tilde{u}_B$, which implies that $\tilde{u}_B(v) > 0$ and $\rho = 1$. If $\mu_i > 1$, then $\mu_i - \rho > 1 - \rho$ and $\mathcal{L}$ is maximized by decreasing $\tilde{u}_B(v)$ to zero and increasing $\tilde{u}_i(\tau)$, contradicting $\tilde{u}_B(v) > 0$, so we have $\mu_i \leq 1$. Further, if $\tilde{u}_i(\tau) > 0$, then
it must be that $\mu_i = \rho = 1$. So, letting $w = (1, \mu_1, \ldots, \mu_n)$, all agents whose worst-off types have a positive interim expected payoff have the maximum bargaining weight of 1. Thus, the payoffs $\tilde{u}$ are generated by $\langle Q^w, M^{w,\eta} \rangle$ with $w = (1, \mu_1, \ldots, \mu_n)$ and for $i \in \mathcal{N}$,

$$
\eta_i = \begin{cases} 
\frac{\bar{u}_i - \mathbb{E}_{v,c}[\Gamma_i(c_i) - c_i]\bar{Q}_i(v, c)}{\mathbb{E}_{v,c}[\sum_{i \in \mathcal{N}}(\Phi(v) - \Gamma_i(c_i))\bar{Q}_i(v, c)]} & \text{if } \mu_i = 1, \\
0 & \text{otherwise},
\end{cases}
$$

and $\eta_B = 1 - \sum_{i \in \mathcal{N}} \eta_i$.

**Case 2:** Suppose that $\mathbb{E}_{v,c}\left[\sum_{i \in \mathcal{N}} (v - \Phi(v))\bar{Q}_i(v, c)\right] = \bar{u}_B$ and that for some $j \in \mathcal{N}$, $\mathbb{E}_{v,c}\left[(\Gamma_j(c_j) - c_j)\bar{Q}_j(v, c)\right] < \bar{u}_j$. Then we can repeat the analysis in Case 1, but centered on supplier $j$ rather than on the buyer, noting that Pareto undominatedness implies that $\bar{u}_j$ solves

$$
\max_{\langle Q, M \rangle \in \mathcal{M}} u_j \text{ s.t. } u_B \geq \bar{u}_B \text{ and for } i \in \mathcal{N}\setminus\{j\}, \bar{u}_j \geq \bar{u}_i.
$$

Then we obtain the analogous result that the payoffs $\tilde{u}$ are replicated by $\langle Q^w, M^{w,\eta} \rangle$ with $w = (\mu_B, \mu_1, \ldots, \mu_{j-1}, 1, \mu_{j+1}, \ldots, \mu_n)$ and

$$
\eta_B = \begin{cases} 
\frac{\bar{u}_B - \mathbb{E}_{v,c}\left[\sum_{i \in \mathcal{N}} (v - \Phi(v))\bar{Q}_i(v, c)\right]}{\mathbb{E}_{v,c}[\sum_{i \in \mathcal{N}}(\Phi(v) - \Gamma_i(c_i))\bar{Q}_i(v, c)]} & \text{if } \mu_B = 1, \\
0 & \text{otherwise},
\end{cases}
$$

for $i \in \mathcal{N}\setminus\{j\}$, $\eta_i$ as given in (20), and $\eta_j = 1 - \eta_B - \sum_{i \in \mathcal{N}\setminus\{j\}} \eta_i$.

**Case 3:** Suppose that $\mathbb{E}_{v,c}\left[\sum_{i \in \mathcal{N}} (v - \Phi(v))\bar{Q}_i(v, c)\right] = \bar{u}_B$ and that for all $i \in \mathcal{N}$, $\mathbb{E}_{v,c}\left[(\Gamma_i(c_i) - c_i)\bar{Q}_i(v, c)\right] = \bar{u}_i$. Then $\bar{u}_B(v) = 0$ and for all $i \in \mathcal{N}$, $\bar{u}_i(\bar{w}) = 0$. It follows that $\rho \geq 1$ and that for all $i \in \mathcal{N}$, $\mu_i \leq \rho$.

**Case 3a:** Suppose that for all $i \in \mathcal{N}$, $\mu_i$ is finite. Letting $\bar{w} \equiv \max\{1, \mu_1, \ldots, \mu_n\}$, $\bar{Q}_i$ is the same allocation rule as $Q^w_i$, where $w = (\frac{1}{\bar{w}}, \frac{\mu_1}{\bar{w}}, \ldots, \frac{\mu_n}{\bar{w}})$, and the payoffs $\tilde{u}$ are replicated by $\langle Q^w, M^{w,\eta} \rangle$ with any specification of $\eta$.

**Case 3b:** Suppose that for some nonempty $\hat{\mathcal{N}} \subseteq \mathcal{N}$, for all $i \in \hat{\mathcal{N}}$, $\mu_i$ is infinite, which implies that $\rho$ is infinite. It follows that the allocation rule $\bar{Q}_i(v, c)$ maximizes $\mathbb{E}_{v,c}[\sum_{i \in \hat{\mathcal{N}}} (\Phi(v) - c_i)\bar{Q}_i(v, c)]$. In this case, $\bar{Q}_i$ is the same allocation rule as $Q^w_i$, where $w_B = 0$, for all $i \in \hat{\mathcal{N}}$, $w_i = 1$, and for all $i \in \mathcal{N}\setminus\hat{\mathcal{N}}$, $w_i = 0$, and the payoffs $\tilde{u}$ are replicated by $\langle Q^w, M^{w,\eta} \rangle$ with any specification of $\eta$.  

**Proof of Proposition 3** The discussion in the text shows that the planner’s and market’s outcomes coincide (up to fixed payments) if (i), (ii), and (iii) hold, implying that $W^w = W^*$.
and so there is no benefit from equalization of bargaining power. It remains to show that $W^w < W^*$ if any one of these conditions fails.

**Case 1.** Suppose that (9) fails, $w_1 = \cdots = w_n = w$, and $G_1 = \cdots = G_n$. Then the planner and market both rank the suppliers the same, but they evaluate either the virtual values or the virtual costs (or both) using different weights because either $w_B \beta^w \neq \beta^1$ or $w_i \beta^w \neq \beta^1$ or both. It follows that $Q^w(v, c) \neq Q^*(v, c)$ for all $(v, c)$ in an open subset of $[\underline{v}, \bar{v}] \times [\underline{c}, \bar{c}]^n$.

**Case 2.** Suppose that (9) holds, $w_1 \neq w_2$ so that (ii) fails, and $G_1 = \cdots = G_n$. Then the planner and market rank the suppliers 1 and 2 differently for $(c_1, c_2)$ in an open subset of $[\underline{c}, \bar{c}]^2$, implying that $Q^w(v, c) \neq Q^*(v, c)$ for all $(v, c)$ in an open subset of $[\underline{v}, \bar{v}] \times [\underline{c}, \bar{c}]^n$.

**Case 3.** Suppose that (9) holds, $w_1 = \cdots = w_n = w$, $w_B > w$, and $G_1 \neq G_2$, so that (iii) fails. Then the planner and market rank the suppliers 1 and 2 differently for $(c_1, c_2)$ in an open subset of $[\underline{c}, \bar{c}]^2$, implying that $Q^w(v, c) \neq Q^*(v, c)$ for all $(v, c)$ in an open subset of $[\underline{v}, \bar{v}] \times [\underline{c}, \bar{c}]^n$. ■

**Proof of Proposition 4.** To begin, note that each point on the frontier is associated with a unique bargaining parameter $\Delta = w_B - w_1 = \cdots = w_B - w_n$. Given bargaining parameter $\Delta$, we denote the associated point on the frontier as $(u_S(\Delta), u_B(\Delta))$, where $u_S$ is the sum of all supplier payoffs.

We first show that $\omega$ is strictly decreasing. If it is not strictly decreasing, then there are two points on the frontier, indexed by $\Delta$ and $\Delta'$, where expected social surplus is strictly greater at the point indexed by $\Delta'$ and expected surplus for both the buyer and the suppliers is weakly greater at the point indexed by $\Delta'$. But then weighted welfare must not have been maximized at the point indexed by $\Delta$ because total surplus could be increased while still satisfying all the constraints and some of that additional surplus could be allocated to one or more of the agents with positive bargaining weight when $w_B - w_S = \Delta$. This completes the proof that $\omega$ is strictly decreasing.

Now turn to the question of concavity. As illustrated in the figure below, suppose that the Williams frontier is not concave.
Then there exist points on the frontier, which we denote by their associated buyer bargaining parameters $\Delta$, $\Delta'$, and $\Delta''$, with $\Delta > \Delta' > \Delta''$, such that $(u_S(\Delta) + u_S(\Delta''))/2 > u_S(\Delta')$ and $(u_B(\Delta) + u_B(\Delta''))/2 > u_B(\Delta')$. Let $\eta(\Delta)$ be the price-formation mechanism associated with bargaining parameter $\Delta$. Then consider the mechanism that is a 50-50 mixture of $\eta(\Delta)$ and $\eta(\Delta'')$. By the construction of the price-formation process, the expected budget surplus to the mechanism in $\eta(\Delta)$, $\eta(\Delta')$, $\eta(\Delta'')$ is zero. The expected weighted welfare under $\eta(\Delta')$ satisfies
\[
\Delta'u_B(\Delta') + \sum_{i \in \mathcal{N}} \frac{1 - \Delta'}{n} u_B(\Delta') < \Delta' \frac{u_B(\Delta) + u_B(\Delta'')}{2} + \sum_{i \in \mathcal{N}} \frac{1 - \Delta'}{n} u_i(\Delta') + u_i(\Delta''),
\]
where the right side is the expected weighted welfare given $\Delta'$ under the mechanism that is a 50-50 mixture of $\eta(\Delta)$ and $\eta(\Delta'')$, which since the no-deficit condition is satisfied, contradicts the optimality of $\eta(\Delta')$. This contradiction completes the proof. ■

**Proof of Proposition 5.** Consider the Bayes Nash equilibrium of the fee-setting game with intermediary preference weights $w$. To begin, we assume that $\pi^w \equiv \mathbb{E}_{v,c}[\sum_{i \in \mathcal{N}} (\Phi(v) - \Gamma_i(c)) \cdot Q_i^w(v,c)] = 0$, and then we address the required adjustments for the case with $\pi^w > 0$ at the end.

Suppose that the intermediary sets auction discounts relative to the clock price $\hat{p}$ of $\delta_i(\hat{p}) \equiv \hat{p} - \Gamma_i^{-1}(c(\hat{p}))$ and a fee schedule given by, for all $i \in \mathcal{N}$,
\[
\sigma_i(p) \equiv \Phi_{i,\beta}^{-1}(\Gamma_i(\beta(\Gamma_i^{-1}(p)))) - p,
\]
and suppose that the buyer sets a reserve of $\Phi_{i,\beta}(v)$. Then, given our assumption that each supplier $i$ follows its weakly dominant strategy of remaining active until a clock price $\hat{p}$
such that \( \hat{p} - \delta_i(\hat{p}) = c_i \), supplier \( i \) remains active until a price of \( \Gamma_{i,w_i\beta^w(c_i)} \), and so supplier \( i \) wins if and only if

\[
\Gamma_{i,w_i\beta^w(c_i)} = \min_{j \in N} \Gamma_{j,w_j\beta^w(c_j)} \leq \Phi_{w_B\beta^w(v)},
\]

which, by Lemma \( \text{[\ref{lemma}]} \) corresponds to the intermediary’s optimal allocation rule, \( Q^w \). In equilibrium, if supplier \( i \) wins the auction, then the auction ends with a clock price of

\[
\hat{p} \equiv \min_{j \in N \setminus \{i\}} \{ \Phi_{w_B\beta^w(v)}, \Gamma_{j,w_j\beta^w(c_j)} \},
\]

and the buyer makes a payment \( p = \hat{p} - \delta_i(\hat{p}) \) to supplier \( i \) and a payment of \( \sigma_i(p) \) to the intermediary.

To summarize, given the suppliers’ optimal bidding strategies and a reserve set by the buyer of \( \Phi_{w_B\beta^w(v)} \), the intermediary’s choice of auction format and fee schedule are optimal because they result in the allocation rule that maximizes the weighted objective subject to no deficit and because the allocation rule pins down the payoffs up to nonnegative constants that are zero under our assumption that \( \pi^w = 0 \). It remains to show that the best response to the intermediary’s auction format and fee schedule for a buyer with value \( v \) is to choose a reserve of \( \Phi_{w_B\beta^w(v)} \).

To reduce notation, let \( x_B \equiv w_B\beta^w \) and \( x_i \equiv w_i\beta^w \). Define the distribution of supplier \( i \)’s weighted virtual type \( \Gamma_{i,x_i}(c_i) \) by

\[
\tilde{G}_{i,x_i}(z) = G_i(\Gamma_{i,x_i}^{-1}(z)),
\]

and, letting \( x \equiv (x_1, \ldots, x_n) \), define the distribution of the minimum of the weighted virtual types of suppliers other than \( i \) by

\[
\tilde{G}_{-i,x}(z) = 1 - \prod_{j \in N \setminus \{i\}} (1 - \tilde{G}_{j,x_j}(z)).
\]
The expected payment by the buyer to the suppliers given the reserve \( r \) can be written as

\[
\sum_{i \in \mathcal{N}} \mathbb{E} \left[ \Gamma_i(c_i) \cdot 1_{\Gamma_{i,x_i}(c_i) \leq \max_{j \neq i} \{r, \Gamma_{j,x_j}(c_j)\}} \right]
\]

\[
= \sum_{i \in \mathcal{N}} \int_{\max\{\xi, \Gamma_{i,x_i}(r)\}}^{\infty} \Gamma_i(c_i) d\tilde{G}_{-i,x}(z) dG_i(c_i)
\]

\[
= \sum_{i \in \mathcal{N}} \int_{\max\{\xi, \Gamma_{i,x_i}(r)\}}^{\infty} \Gamma_i(c_i)(1 - \tilde{G}_{-i,x}(\Gamma_{i,x_i}(c_i))) dG_i(c_i)
\]

\[
= \sum_{i \in \mathcal{N}} \int_{\max\{\xi, \Gamma_{i,x_i}(r)\}}^{\infty} y \left[ 1 - \tilde{G}_{-i,x}(\Gamma_{i,x_i}(\Gamma_i^{-1}(y))) \right] g_i(\Gamma_i^{-1}(y)) \frac{1}{\Gamma_i(\Gamma_i^{-1}(y))} dy,
\]

where the final equality uses the change of variables \( y = \Gamma_i(c_i) \). Thus, the buyer with value \( v \) maximizes its interim expected payoff by choosing \( r \) to solve

\[
\max_r \sum_{i \in \mathcal{N}} \left( \int_{\xi}^{\max\{\xi, \Gamma_i(\Gamma_i^{-1}(r))\}} (v - y - \sigma_i(y)) \left[ 1 - \tilde{G}_{-i,x}(\Gamma_{i,x_i}(\Gamma_i^{-1}(y))) \right] g_i(\Gamma_i^{-1}(y)) \frac{1}{\Gamma_i(\Gamma_i^{-1}(y))} dy \right),
\]

which, when \( \xi < \Gamma_i(\Gamma_i^{-1}(r)) \), has first-order condition

\[
0 = \sum_{i \in \mathcal{N}} \Gamma_i(\Gamma_i^{-1}(r)) \Gamma_i^{-1}(r) \left( (v - \Gamma_i(\Gamma_i^{-1}(r)) - \sigma_i(\Gamma_i(\Gamma_i^{-1}(r)))) \right) \left( 1 - \tilde{G}_{-i,x}(r) \right) g_i(\Gamma_i^{-1}(r)) \frac{1}{\Gamma_i(\Gamma_i^{-1}(r))}
\]

\[
= \sum_{i \in \mathcal{N}} \Gamma_i(\Gamma_i^{-1}(r)) \Gamma_i^{-1}(r) \left( v - \Phi_{-i,x}(r) \right) \left( 1 - \tilde{G}_{-i,x}(r) \right) g_i(\Gamma_i^{-1}(r)) \frac{1}{\Gamma_i(\Gamma_i^{-1}(r))},
\]

where the second equality uses the definition of the fee schedule \( \sigma \). Given our assumptions, the second-order condition is satisfied when the first-order condition is, and so the buyer’s problem is solved by \( r = \Phi_{-i,x}(v) = \Phi_{-i,x}(\Phi_{-i,x}(v)) \), giving the buyer nonnegative interim expected payoff, which completes the proof for the case with \( \pi^w = 0 \). If \( \pi^w > 0 \), then this “excess profit” must be distributed via fixed payments between the agents and the intermediary so that the worst-off type of each agent \( i \in \{\mathcal{B} \} \cup \mathcal{N} \) has interim expected payoff \( \eta_i \pi^w \).

**Proof of Proposition 8** With nonoverlapping supports and symmetric bargaining weights, the pre-integration market achieves the first-best. After integration between the buyer and supplier \( i \), the buyer’s willingness to pay is the cost realization of the integrated supplier, that is, \( c_i \), whose support is \([\xi, \bar{c}]\). Thus, we have a generalized Myerson-Satterthwaite problem (generalized insofar as there is one buyer but \( n - 1 \geq 1 \) suppliers). For this setting,
impossibility of first-best trade obtains (see, e.g., Delacrétaz et al., 2019), regardless of bargaining weights. ■

Proof of Proposition 9. Suppose that first-best investments $\bar{e}$ are Nash equilibrium investments. Because $\bar{e}$ are first-best investments and by the definition of $W_{FB}(v, c)$,

$$e_B \in \arg \max_{e_B} \mathbb{E}_{v, c \mid e_B} \left[ (v - \min c) \cdot \mathbf{1}_{v \geq \min c} - \Psi_B(e_B) \right]. \hspace{1cm} (21)$$

Consider the outcome of incomplete information bargaining. By the payoff equivalence theorem, we can without loss consider the dominant-strategy implementation. In that case, if $Q^w_B(v, c) = 1$, then $M^w_B(v, c)$ is equal to the buyer’s threshold type

$$\tau_B(c) \equiv \inf \{ x \in [\underline{v}, \overline{v}] \mid Q^w_B(x, c) = 1 \},$$

and is zero otherwise. By the supposition that $\bar{e}$ is a Nash equilibrium, $e_B$ is a best reply to $e_{-B}$, which implies that

$$\tau_B(c) = \min c \text{ for all but a zero-measure set of types, which implies that bargaining is efficient. Thus, if first-best investments $\bar{e}$ are a Nash equilibrium, then incomplete information bargaining is efficient. ■}$$

Proof of Lemma 2. The extension to allow supplier specific quality parameters follows by analogous arguments to Lemma 1 noting that the buyer’s value for supplier $i$’s good is $\theta_i v$, which has distribution $\hat{F}(x) \equiv F(x/\theta_i)$ on $[\theta_i \underline{v}, \theta_i \overline{v}]$ with density $\hat{f}(x) = \frac{1}{\theta_i} f(v/\theta_i)$. Thus, the virtual type when the buyer’s value is $v$ is

$$\hat{\tau}_i v - \frac{1 - \hat{F}(\hat{\tau}_i v)}{\hat{f}(\hat{\tau}_i v)} = \hat{\tau}_i v - \hat{\tau}_i \frac{1 - F(v)}{f(v)} = \hat{\tau}_i \Phi(v).$$

Thus, the parameter $\theta_i$ “factors out” of the virtual type function. The extension to multi-object demand follows by standard mechanism design arguments. ■
C Appendix

For the case of one supplier, the allocation $Q_i^w(v,c)$ is the same for all $w$ with the same bargaining differential $\Delta$ defined by

$$\Delta = \frac{w_B - w_1}{\max\{w_B, w_1\}} \in [-1, 1].$$

Further, we can span $\Delta \in [-1, 1]$ with bargaining weights $(w_B, w_1)$ satisfying $\max\{w_B, w_1\} = 1$, so we restrict attention to such $(w_B, w_1)$ in what follows. Under this restriction, there is a one-to-one mapping between $(w_B, w_1)$ and $\Delta$.

Under the assumption of one supplier and uniformly distributed types, for all $w$, $\beta^*(w)$ is such that

$$0 = \mathbb{E}_{v,c}[(\Phi(v) - \Gamma(c)) \cdot Q_i^w(v,c)]$$

$$= \int_{\frac{1-w_B\beta^w}{2-w_B\beta^w}}^{1} \int_{0}^{\frac{v-(1-w_B\beta^w)(1-v)}{2-w_S\beta^w}} (2v - 1 - 2c) dc dv,$$

where the second equality uses the expression for $Q_i^w(v,c)$ from Lemma 1. Solving this for $\beta^w$ and using $\max\{w_B, w_S\} = 1$, we get

$$\beta^w = \begin{cases} \frac{2w_B+2w_S-2\sqrt{w_B^2-w_B w_S+w_S^2}}{3w_B w_S} & \text{if } 0 < \min\{w_B, w_S\}, \\ 1 & \text{if } 0 = \min\{w_B, w_S\}. \end{cases}$$

Making the substitution $\Delta = w_B - w_S$ and writing $\beta^w$ as a function of $\Delta$, we have $\beta^\Delta = 1$ for $\Delta \in \{-1, 1\}$ and otherwise $\beta^\Delta$ is given by:

$$\beta^\Delta = \frac{4 - 2|\Delta| - 2\sqrt{1 - |\Delta| + \Delta^2}}{3(1 - |\Delta|)}. \quad (23)$$

It is then straightforward to derive, for a given $\Delta$, the conditions on $(v,c)$ such that there is trade. Equating this condition with the condition for trade in the $k$-double auction allows one to identify the relation between $\Delta$ and $k$ as

$$\Delta_k \equiv \frac{1 - 2k}{k^2 - \max\{1, 2k\}}. \quad (24)$$

We now show that the price-formation mechanism with bargaining differential $\Delta_k$ is equivalent to the $k$-double auction. Substituting the expression for $\beta^\Delta$ in place of $\beta^w$ into the expression derived from Lemma 1 for $Q_1^{(1+\Delta,1)}(v,c)$ if $\Delta \in [-1,0]$ and for $Q_1^{(1,1-\Delta)}(v,c)$
if $\Delta \in (0, 1]$ , we have

$$Q^{\Delta}(v, c) \equiv \begin{cases} 
1 & \text{if } \Delta \in (-1, 0] \text{ and } v \geq \frac{2c(\sqrt{\Delta^2+1}+2\Delta+1)+2\sqrt{\Delta^2+1}}{2(\Delta+1)(\sqrt{\Delta^2+1}+\Delta+1)} \cdot (\Delta+1), \\
\text{or if } \Delta \in [0, 1) \text{ and } v \geq \frac{2c(\sqrt{\Delta^2-\Delta+1}+1)}{2(\sqrt{\Delta^2-\Delta+1}+\Delta+1)} \cdot (1-\Delta)+2\sqrt{\Delta^2-\Delta+1}-\Delta \cdot \delta_{|X|}, \\
\text{or if } \Delta = 1 \text{ and } v \geq 2c, \\
\text{or if } \Delta = -1 \text{ and } v \geq \frac{c+1}{2}, \\
0 & \text{otherwise.}
\end{cases}$$

It then follows that $Q^{\Delta}(v, c)$ is the same allocation rule as for the $k$-double auction, i.e., there is trade if and only if $v \geq \frac{c+1+k}{2}$.  

D Appendix: Generalization

Let $\mathcal{P}$ be the set of subsets of $\mathcal{N}$ with no more than $D$ elements (including the empty set) and let $\theta = \{\theta_X\}_{X \in \mathcal{P}}$ be a commonly known vector of taste parameters of the buyer satisfying the “size-dependent discounts” condition of Delacrétaz et al. (2019). Specifically, let there be supplier-specific preferences $\{\hat{\theta}_i\}_{i \in \mathcal{N}}$ and size-dependent discounts $\{\delta_i\}_{i \in \mathcal{N}}$ with $0 = \delta_0 = \delta_1 \leq \delta_2 \leq \cdots \leq \delta_n$ such that for all $X \in \mathcal{P}$, $\theta_X = \sum_{i \in X} \hat{\theta}_i - \delta_{|X|}$. Thus, the buyer’s value for purchasing from suppliers in $X \in \mathcal{P}$ when its type is $v$ is $\theta_X v$, which depends on the buyer’s value, the buyer’s preferences for standalone purchases from the suppliers in $X$, and a discount that depends on the total number of units purchased. Note that $\theta_\emptyset = 0$, so that the value to the buyer of no trade is zero.

This setup encompasses (i) the homogeneous good model with constant marginal value or decreasing marginal value by setting $\hat{\theta}_i = \theta$ for some common $\theta$ and for $i \in \mathcal{N}$, $\delta_i$ either all zero for constant marginal value or increasing in $i$ for decreasing marginal value; (ii) differentiated products by letting $\hat{\theta}_i$ differ by $i$ and setting all $\delta_i$ to zero; (iii) a one-buyer version of the Shapley-Shubik model by setting $D = 1$; and (iv) a version of the Shapley-Shubik model in which the buyer has demand for multiple products of the suppliers by setting $D > 1$.

Define

$$X^*_\beta(v, c) \in \arg \max_{X \in \mathcal{P}} \theta_X \Phi_\beta(v) - \sum_{i \in X} \Gamma_{i,\beta}(c_i),$$

i.e., $X^*_\beta(v, c)$ is the set of trading partners for the buyer that maximizes the difference between the ironed $\beta$-weighted virtual value, scaled by $\theta_{X^*_\beta(v, c)}$, and the ironed $\beta$-weighted virtual costs.
of the trading partners. We then define $\beta^*$ to be the largest $\beta \in [0, 1]$ such that

$$\mathbb{E}_{v,c} \left[ \theta_{X^*_\beta(v,c)} \Phi(v) - \sum_{i \in X^*_\beta(v,c)} \Gamma_i(c_i) \right] = 0.$$ 

Given the type realization $(v, c)$, the one-to-many $\beta^*$-mechanism induces trade between the buyer and suppliers in $X^*_\beta(v,c)$. The expected payoff of the buyer is

$$\mathbb{E}_v \left[ \hat{u}_B(v) + \int_v^\infty \sum_{X \in P} \theta_X \Pr_c \left( X \in X^*_\beta(x,c) \right) dx \right],$$

and the expected payoff of supplier $i$ is

$$\mathbb{E}_{c_i} \left[ \hat{u}_i(v) + \int_{c_i}^\infty \Pr \left( i \in X^*_\beta(v,x,c_{-i}) \right) dx \right].$$

### E Appendix: Bargaining externalities

In this appendix, we adopt the generalized setup of Section 5.3 with multi-unit demand and buyer preferences over suppliers and illustrate bargaining externalities.

In Table 1, we consider the case of one buyer and two suppliers with symmetric bargaining weights. Assuming that $F$, $G_1$, and $G_2$ are the uniform distribution on $[0, 1]$, and assuming that $\theta_2 = 1$, we allow the buyer’s preference for supplier 1, $\theta_1$, and the buyer’s total demand, $D$, to vary.

<table>
<thead>
<tr>
<th>$\theta_1$</th>
<th>$D = 1$</th>
<th>$D = 2$</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0.73</td>
<td>0.67</td>
</tr>
<tr>
<td>2</td>
<td>0.76</td>
<td>0.72</td>
</tr>
</tbody>
</table>

As shown in Table 1, focusing on the case with $D = 1$, an increase in the buyer’s preference for supplier 1 from $\theta_1 = 1$ to $\theta_1 = 2$ benefits supplier 1 ($u_1$ increases) but harms supplier 2.
(\(u_2\) decreases). The increase in the buyer’s preference for supplier 1 means that supplier 2 is less likely to trade. As a result, supplier 2 is harmed by the increase in the buyer’s preference for supplier 1. But when \(D = 2\), the results differ. Supplier 1 again benefits from being preferred by the buyer, but in this case supplier 2 also benefits, albeit less than supplier 1. The increase in the buyer’s value from trade with supplier 1 means that the value of \(\beta^{w,\theta}\) increases, so supplier 2 trades more often. As a result of the change from \(\theta_1 = 1\) to \(\theta_1 = 2\), both \(u_1\) and \(u_2\) increase.

\section*{F Appendix: (Unique) properties of the IPV paradigm}

The independent private values setting with continuous distributions has the virtue that, for a given objective, the mechanism that maximizes this objective, subject to incentive-compatibility, individual-rationality, and no-deficit constraints, is well defined and pinned down (up to a constant in the payments) by the allocation rule, which is unique. Of particular interest to industrial organization and antitrust economics, it also has the feature that, quite generally, there is a tradeoff between allocating efficiently and extracting rents. This tradeoff is at the heart of both industrial organization and Myerson’s optimal auction. This tradeoff is the reason why the Williams frontier is typically not identical to the 45-degree line and, therefore, the basis from which the possibility of social surplus increasing countervailing power emerges.

Privacy of information endows economic agents with information rents and thereby protects them from hold up, as discussed in our analysis of investments. Even without investment, this protection implies, for example, that first-degree price discrimination is not possible. Rather than being an assumption, the impossibility of first-degree price discrimination is an implication in this setup. Likewise, setting a uniform market clearing price is the optimal mechanism for a monopoly with constant marginal costs facing a continuum of buyers, so under these conditions uniform pricing is a conclusion rather than an assumption. Moreover, the aforementioned assumptions are essentially the only assumptions that permit a tractable approach that maintain the basic tradeoff between profit and social surplus. Dropping the assumption of risk neutrality, Maskin and Riley (1984) and Matthews (1984) show that optimal mechanisms depend on the nature of risk aversion, are not easily characterized, and, among other things, may require payments to and/or from losers. Without independence, as foreshadowed by Myerson (1981), Crémer and McLean (1985, 1988) show that there is no tradeoff between profit and social surplus. Without private values,

\[54\]

In contrast, if the monopoly has increasing marginal costs and the revenue function that it faces is not concave, then setting non-market-clearing prices may be optimal (see Loertscher and Muir, 2019).
additional and, therefore, in some sense arbitrary, restrictions may be required to maintain tractability and/or the tradeoff between profit and social surplus (Mezzetti 2004, 2007). Notwithstanding recent progress, with multi-dimensional private information and multiple agents, the optimal mechanism is not known (see, e.g., Daskalakis et al., 2017). With discrete types, there is no payoff equivalence theorem. In other words, the mechanism is not pinned down by the allocation rule.
