This research was partially funded by the MIT Center for Innovation in Product Development (CIPD), the MIT eBusiness Center, the Singapore-MIT Alliance and NSF grant DMI-0322823. The paper has benefited from comments by John Hauser, Shie Mannor, Olivier Toubia and workshop participants at Duke University, Queens University, MIT, Texas A&M, University of Chicago, University of Florida, University of Iowa, University of Western Ontario, the 2002 Fall INFORMS Conference and the Winter 2003 National Center for Database Marketing (NCDM) Conference. We also gratefully acknowledge the contribution of the company that provided the data for this study and research assistance from Stephen Windsor.
Dynamic Catalog Mailing Policies

Deciding who should receive a mail-order catalog is amongst the most important decisions that mail-order catalogs must address. In practice, the current approach to the problem is invariably myopic: firms send catalogs to customers who they think are most likely to order from that catalog. In doing so, the firms overlook the long-run implications of these decisions. For example, it may be profitable to mail to customers who are unlikely to order immediately if sending the current catalog increases the probability of a future order. We propose a model that allows firms to optimize mailing decisions by addressing the dynamic implications of their decisions. The model is conceptually simple and straightforward to implement. We apply the model to a large sample of historical data provided by a catalog firm and then evaluate its performance in a large-scale field test. The findings offer support for the proposed model, but also identify opportunities for further improvement.
1. Introduction

Catalog firms mailed almost 17 billion catalogs in 2000 (DMA 2000). To determine who should receive these catalogs, firms typically estimate the probability that a customer will purchase from historical data. They then mail catalogs to all customers for whom this probability exceeds the breakeven level, at which mailing costs equal expected profits. In doing so firms focus solely on the response to the next catalog, overlooking any long-term effects on demand. Yet there is considerable evidence that receiving a catalog has an enduring impact on customer purchasing behavior beyond the current period. These long-term effects are well illustrated by the findings of a pilot study conducted with the women’s clothing catalog that provided the data for this paper (see later discussion). In this pilot study, which provided the motivation for this research, 10,000 of the catalog’s past customers were randomly assigned to equal-sized Test and Control groups. The 5,000 customers in the Test Group received all seventeen catalogs mailed by the firm over a nine-month period, while customers in the Control group received just nine of the seventeen catalogs. In Figure 1 we summarize the average monthly revenue earned from each sample both during the 9-month test period and over the 9-months following the test period.

Figure 1: Pilot Study Results
Unsurprisingly, the higher frequency of mailings to the Test customers yielded higher revenue from these customers during the (shaded) test period. More notably, this lift in revenue persisted beyond the test period. Monthly revenue earned from the Test Group was still higher nine months after the test had finished, even though the same mailing policies were used for both groups in this post-test period. Evidence that current mailing decisions affect future demand is consistent with an interpretation that catalogs serve as an advertising vehicle, exposing customers to the firm’s brand and products. In making purchasing decisions we would expect customers to use their entire stock of experience, including exposure to prior catalogs.

The evidence that mailing decisions affect future demand also has important implications for mailing policies. In particular, the findings in Figure 1 suggest that it may be profitable to mail to customers who are unlikely to respond to the current catalog if it increases the likelihood that they will respond to future catalogs. The mailing strategies currently used in the industry generally ignore these long-run effects. Firms may occasionally compare different sequences of mailing decisions using randomly selected customer samples (as in the pilot study). However, the very large range of possible sequences makes it infeasible to identify an optimal policy through this approach. Moreover, evaluating long-run outcomes requires waiting for the long-run to occur, further hindering firms’ abilities to identify optimal dynamic policies through traditional split-sample testing.

We propose a model that allows firms to address the dynamic implications of mailing decisions. In developing this model we have several goals. First, the model is intended to be managerially relevant - it is conceptually simple and straightforward to implement. Second, we seek a model that is modular in the components of the model that firms may choose to implement. As we will discuss the model has two components: (a) the design of a discrete state space and (b) the optimization of the mailing policy on that state space. There are alternative procedures that can be used to perform each component and these alternatives are substitutable. For example, firms may choose an alternative method to design the state space, while using the procedures that we propose for optimizing the mailing policy (and vice versa). Third, we would also like the model to be modular in the segments of customers that firms choose to implement it on. A firm may choose to implement the proposed model on customers with some characteristics, while retaining its current policy for other customers. Because the characteristics of the customers change over
time, this modularity requires that the model explicitly take into account the possibility that the
customers will shift between policies. Our final goal focuses on validation. To validate the
proposed model we use both historical data and a large-scale field test.

Data Requirements

The proposed model requires data describing both the mailing history and the transaction history
for each customer.\(^1\) Although maintaining a record of a customer’s mailing history is no more
difficult than maintaining a record of the customer’s purchase history, many catalog retailers do
do not store complete mailing histories. This might be interpreted as an explanation for why the
mailing history is typically not used to design the mailing policy. It is more likely that the
causation operates in the reverse; many firms do not store the mailing history because they do
not use it. One explanation for this omission is that the mailing history is highly correlated with
the purchase history, so that the purchase history provides a sufficient statistic. However, in
practice, stochasticity in the mailing policy ensures that the purchase history is not a sufficient
statistic.

The proposed model requires stochasticity in the historical mailing policy. For example, if the
firm historically only mailed to customers who had recently purchased, then the model cannot
predict how other customers would respond if mailed. Fortunately, there is often considerable
stochasticity in historical mailing policies. There are at least two primary sources for this
stochasticity. First, stochasticity is introduced by regular randomized split-sample testing (such
as the pilot study). The company that provided data for this study regularly conducts these types
of tests and discussions with other catalog companies confirm that the practice is widespread.
The second source of variation in mailing policies reflects changes in the mailing policy over
time due to changes in the models used to predict customer response rates. The company
employs a staff of analysts who are continually searching for opportunities to improve the
profitability of the firm’s mailing policies. Together with other changes in management policies
and personnel, this leads to ongoing changes in the mailing policy.

---
\(^1\) Because dynamic considerations have little influence on mailing policies for prospective customers we restrict
attention to past (house) customers. For prospective customers the dynamics are only relevant to the extent that they
change the value of acquiring a customer.
The requirement for stochasticity in the historical mailing policy in part explains the desire for a model that is modular in the segments of customers that firms choose to implement it on. The level of stochasticity in the historical policy will often vary across customers with different characteristics. For example, in the sample of historical data used in this study, the firm mailed to an average of 59% of its customers in each time period. However, for some of the most valuable customers this percentage increased to 93%, while it was as low as 9% for some of the less valuable customers. Modularity allows for restricting application of the model to states in which there is sufficient stochasticity.

**Literature**

There is an extensive literature investigating topics relevant to the catalog industry. This includes a series of studies that use catalog data to investigate pricing cues and the impact of price promotions (see for example Anderson and Simester 2004). Other topics range from customer merchandise returns (Hess and Mayhew 1997), to customer privacy (Schoenbachler and Gordon 2002) and catalog copy issues (Fiore and Yu 2001).

There have also been several prior studies investigating optimal catalog mailing strategies. Bult and Wansbeek (1995) present a model for making mailing decisions that builds on work by Banslaben (1992). They develop a model to predict whether customers will respond to a catalog and link the model to the firm’s profit function in order to derive a profit maximizing decision rule. They evaluate their model using a sample of historical data provided by a direct marketing company selling books, periodicals and music in the Netherlands. They show that their methodology offers strong predictive accuracy and the potential to generate higher net returns than traditional approaches.

Bitran and Mondschien (1996) focus on the role of cash flow constraints when making catalog mailing decisions. The cash flow constraint introduces a tradeoff between mailing to prospective customers and mailing to house customers. Mailing to prospective customers is an investment that yields negative cash flow in the short term but builds the company’s house list, while mailing to the house list enables the firm to harvest value from its earlier investments. The model incorporates inventory decisions, so that the profitability of the mailing policy depends
Gönül and Shi (1998) propose a model of mailing policies that explicitly recognizes that a mailing policy may affect demand beyond the current period. Amongst academics this is perhaps the most widely known contribution to the catalog-mailing literature and its objective is closely related to this paper. Drawing on the structural dynamic programming literature (see for example Rust 1994) Gönül and Shi propose a model in which customers optimize a stochastic and dynamic Markov game. In particular, the model assumes that customers understand both the firm’s mailing strategy and the stochasticity in their own purchasing decisions. Among other factors, customer utility is an increasing function of whether they receive catalogs and so it is assumed that customers contemplate how their purchasing decisions will affect the likelihood that they will receive catalogs in the future. For any value of the parameters of the customer utility function, a value function is defined, which corresponds to the solution of the postulated stochastic game. This value function results in a model of firm and customer behavior. The “true” parameters of the utility function are estimated using maximum likelihood by comparing the behavior predicted by the model with available data. The authors test their predictions using the purchase histories for 530 customers of a durable household goods retailer. The findings suggest that their proposed policy has the potential to increase the firm’s profits by approximately 16%.

If their assumptions hold, Gönül and Shi’s approach offers an important advantage over the model that we propose: it provides a means of predicting how customers will behave under mailing policies that do not arise in the historical data. As such, it does not require the same level of stochasticity in the historical policy as the proposed model. For example, even if the company only mailed to customers who had recently purchased, the response model provides a means of estimating how other customers would respond if mailed. Of course, these predictions will be more accurate if there is stochasticity in the historical policy, so that there are past examples of mailing to all types of customers.

These benefits come at some cost. First, as Gönül and Shi acknowledge, computation is very difficult when there are more than two state variables. In practice, firms often use a rich array of
historical measures when designing their mailing policies. Second, the model depends upon the specification of the utility function and an assumption that in the available data customers derive both the optimal mailing policy for the firm and their own optimal dynamic policy. This assumption that customers derive the optimal policy for the firm appears strong in light of the paper’s conclusion that the firm does not optimize its own mailing policy. Third, the response function simply predicts whether a customer will purchase and does not consider the magnitude of that purchase.\(^2\) In practice, we would also like to consider the size of customers’ orders. Finally, the model requires that the data identify which catalog a customer ordered from. As we will discuss, this also raises practical difficulties. Customers often do not have the catalog code when they are placing an order so that it is not possible to link transactions with specific catalogs. Discussions with different catalog managers reveal that the Internet has greatly aggravated this problem, as customers can use the Internet as an ordering mechanism without reference to a catalog.

For these and other reasons, the Gönül and Shi model has attracted more attention from academics than practitioners. In part this reflects a difference in objectives. The structural dynamic programming literature has traditionally focused on understanding what factors affect customer or firm decision-making. Agents are assumed to be optimizing dynamically and the model then searches for parameters that yield the observed behavior as an optimal outcome. In this paper we have a different objective. We propose a model with additional practical relevance that is conceptually simple and straightforward to implement. The proposal uses a different approach to overcome the practical limitations in the Gönül and Shi model. As we will discuss, we calculate transition probabilities and one-step rewards directly from the data. This direct (non-parametric) estimation of the customers’ response function from the data does not impose functional form assumptions and allows us to greatly expand the dimensionality of the problem. The method has its own limitations, which we identify and propose solutions for.

Finally, in a very recent paper, Elsner, Krafft and Huchzermeier (2003) present a description of the success that Rhenania, a German catalog company, enjoyed when implementing a dynamic approach to optimizing catalog mailing policies. They used a lengthy series of split-sample

\(^2\) In an Appendix Gönül and Shi briefly describe an extension to their model that considers how much customers spend on each purchase (where the amount spent is discretized into \(k\) brackets). However, computational limitations prevented estimation of this model.
mailing tests to estimate the response to different mailing frequencies together with a Chi-Square Automatic Interaction Detection (CHAID) algorithm to segment customers. Implementation of the approach required several years but yielded dramatic improvements in profitability. Details of the approach are not provided, but it is clear that the approach differs in many respects from the method proposed in this paper. For example, it does not appear that Rhenania explicitly estimated a value function. Moreover, as long as there is sufficient stochasticity in the historical data, the method that we propose can be implemented without a lengthy sequence of initial tests. However, from their findings it is clear that Rhenania was able to increase its profits by mailing to low-valued customers even though these customers were unlikely to respond immediately. This can be interpreted as evidence that it is more profitable to optimize over the long run rather than simply optimizing myopically.

2. Overview of the Proposed Model

Before presenting the proposed model it is helpful to begin by providing a brief overview and several definitions. We interpret the company’s sequence of mailing decisions as an infinite horizon task (there is no end point) and seek to maximize the discounted stream of expected future profits. Time is measured in discrete periods defined by exogenously determined catalog mailing dates. The intervals between mailing dates typically vary and so we will allow time periods to have different lengths. We use the term “reward” to describe the profit earned in any time period \( r_t \). This reward is defined as the net profit earned from a customer’s order (if any) less mailing costs (if a catalog was mailed that period).

Customers’ histories (and their current status) will be described at each time period by a set of \( n \) variables, so that a point in an \( n \)-dimensional space represents each customer at each time period. The vector space \( X \) is the Cartesian product of the ranges of the \( n \) variables. We will segment the space into mutually exclusive and collectively exhaustive discrete states. Intuitively, the states group together neighboring observations (customers at each time period) that have comparable histories and are expected to respond in a similar way to future policies. Obviously, the design of the states is an important challenge, which we address in Section 3.

There are two possible actions at each time period: mail or not mail. We identify the action at time period \( t \) by \( a_{ts} \in \{0,1\} \), where \( a_{ts} = 1 \) denotes a decision to mail at time period \( t \) to every
customer in state \( s \). A policy \((\pi)\) describes a mailing decision for each state. The firm’s objective is to choose a policy that maximizes the following objective function:

\[
V^n(s) = \sum_{t=1}^{\infty} \delta^T r_t^n(s) \quad \forall s.
\]  

(1)

Because the length of the time periods may differ, we define \( T \) as the number of days between the beginning of the initial time period and the end of the \( t^{th} \) time period, and \( \delta \) as a discount factor. Here, \( r_t^n(s) \) is the immediate reward expected in time period \( t \), under policy \( \pi \), given the initial state at period zero was \( s \).

We attribute purchases to the time periods in which they occurred, rather than the date of the catalog that the customer ordered from. This offers three advantages. First, it overcomes the practical problem described in the previous section, that it is often difficult to link a purchase to a specific catalog. This problem arises for approximately 15% of the purchases in our dataset. This percentage is larger in the more recent data (and is expected to grow) due to an increase in the number of orders placed over the Internet channel. Second, attributing profits to the time period in which they occurred, rather than the date of the catalog, overcomes the need to explicitly consider cannibalization across catalogs. A customer who is ready to purchase will often purchase from a prior catalog if they do not receive the most recent catalog. As a result, customers may be less likely to purchase from a prior catalog if they are mailed another catalog two weeks later. If we attribute purchases to specific catalog, when evaluating the profitability of each mailing we would need to account for the adverse impact of this mailing decision on the profitability of previous mailing decisions. This problem does not arise if we record purchases in the period they are earned irrespective of which catalog they are ordered from. Finally, treating purchases as a consequence of the stock of prior mailing decisions rather than a specific mailing decision is more consistent with our claim that the effect of mailing a catalog to a customer extends beyond the immediate purchase occasion. Customers’ experiences with a catalog are not limited to the catalog that they ordered from, and so their purchasing decisions are not determined solely by that mailing decision.
Structure of the Paper

In the next section we propose an algorithm for designing a discrete space and in Section 4 we describe a dynamic programming algorithm to compute the optimal policy and the value function associated with this policy. We emphasize that these components are modular, and so, for example, the dynamic programming algorithm can be used with a different algorithm for designing the state space. In Section 5 we describe the application of the model to a sample of historical data provided by a catalog company that sells women’s apparel and then in Section 6 we describe the validation of the model through a large-scale field test. Finally, the paper concludes in Section 7 with a discussion of the findings and implications for future research.

3. Constructing the State Space

The standard industry approach to designing a discrete state space is to tile the (continuous) state variables. There are several difficulties with this approach. Notably, it can yield a large number of states, and observations are often unevenly distributed across these states (many states are populated with few or no observations). An alternative approach is to develop a predictive model of how likely customers are to respond to a catalog and to discretize predictions from this model. The DMA reports that this approach, which will tend to yield fewer more evenly distributed segments, is used by approximately 28% of catalog firms (DMA 2001). However, while this alternative is well-suited to a myopic mailing policy, it is not well suited to a dynamic policy. There is no guarantee that grouping customers according to the predicted response to the next catalog will allow the model sufficient discrimination in a dynamic context. In particular, a new customer with few prior purchases may have the same purchase probability as an established customer who has extensive experience with the catalog. Yet the long-term benefits of mailing the established customer may be different than the benefits of mailing the new customer.

In proposing a new algorithm for constructing a discrete state space we adopt three objectives. First, the states should be “meaningful”, so that each state \( s \in S \) contains observations in the historical data. Second, the states should be “representative”, so that data points in the same state are geometrically close to each other. Finally, the states should be “homogenous,” so that the observations within a state share a similar profit stream given an identical mailing policy.
We begin by initially estimating a value function for each customer under the historical mailing policy. For a customer at point \( x \in X \), let \( \tilde{V}^{\pi_H}(x) \) be an estimate of the present value of the expected discounted future profit stream under the historical mailing policy. Here \( \pi_H \) indicates the historical mailing policy and the tilde denotes the initial estimation. If the period of time covered by the historical data is sufficiently long, this estimate can be derived by fitting a function of the discounted aggregate profits earned for a representative sample of customers (see the implementation discussion in Section 5). Given \( \tilde{V}^{\pi_H}(x) \) we use a series of separating hyperplanes to divide the state space into pieces organized by a binary tree structure.

We illustrate the intuition for the binary tree structure in Figure 2. Assume that we describe customers’ history using just two variables \( n = 2 \). A sample of data represented in this two dimensional \( X \) space is portrayed in Figure 2a. Line 1 represents a hyperplane in this \( X \) space that separates the sample in two sub-segments (Figure 2b). The next iteration begins by selecting the segment with the highest variance for \( \tilde{V}^{\pi_H} \) (not shown) and placing a second separating hyperplane (Line 2) through this segment. Following this second iteration there are a total of three segments (see Figure 2c). The process continues until a stopping rule is met, such as the desired number of segments or an upper bound on the largest variance in \( \tilde{V}^{\pi_H} \) within any state.

The outcome is a tree-structure (Figure 2d), where the hyperplanes are branches on the tree and the segments are the leaves. A state space with \( N \) segments requires a tree with \( N-1 \) hyperplanes. Given the tree structure, the path from the root to each leave node defines a set of inequalities identifying each state. Aggregation of states is also easily accomplished by pruning a large tree structure to a smaller one. This use of a binary tree structure is similar in spirit to the decision tree methods for classification (Duda, Hart and Stork 2000) and the Chi-Square Automatic Interaction Detection (CHAID) methods in customer segmentation (see for example Bult and Wansbeek 1995). The primary difference between the methods is the design of the hyperplanes determining the branches.
The algorithm that we use for identifying the hyperplanes proceeds iteratively, where each iteration has two steps. First, we select the segment for which the variance in \( \bar{V}^\pi_j(x) \) is the largest. Formally, we select the segment \( X_j \) for which \( \sum_{x \in X_j} \left( \bar{V}^\pi_j(x) - \bar{V}_{X_j} \right)^2 \) is largest, where \( \bar{V}_{X_j} \) is the average of \( \bar{V}^\pi_j(x) \) calculated over all \( x \in X_j \). This criterion favors the selection of segments that are least homogenous and/or have the most members. To prevent states with very few observations we only select from amongst segments with at least 1,000 observations in them.

In the second step, we divide \( X_j \) into two segments \( X_j' \) and \( X_j'' \). To satisfy the homogeneity criterion, we would like the observations within each sub-segment to have similar values of \( \bar{V}^\pi_j(x) \). To achieve this we could fit a step function to the \( \bar{V}^\pi_j(x) \) values in \( X_j \). However, computationally this is a difficult problem, and so we use a heuristic to approximate this step. The heuristic uses the following steps:
1. Use OLS to estimate $\alpha$ and $\beta$ in $\tilde{V}^{\pi_h} = \alpha + \beta^T x + \varepsilon$ using all $x \in X_i$. That is, we find $\alpha$ and $\beta$ that minimize $\sum_{x \in X_i} \left( \tilde{V}^{\pi_h}(x) - \alpha - \beta^T x \right)^2$.

2. Find the center of the observations in the segment, $\bar{x} = \sum_{x \in X_i} x$, by calculating the average of the observations on each of the $n$ state variables.

3. Compute $\alpha'$ such that $\alpha' + \beta^T \bar{x} = 0$ and divide segment $X_i$ into two segments $X_i'$ and $X_i''$ along the hyperplane defined by $\alpha' + \beta^T x = 0$.

We can again illustrate this process using a 2-dimensional $X$ space (see Figure 3). In Figure 3a we depict the observations in a selected segment. The center of these observations is defined by $\bar{x}$ and each observation has an estimated $\tilde{V}^{\pi_h}$ (Figure 3b). We use OLS to regress $\tilde{V}^{\pi_h}$ on $x$, which we illustrate in Figure 3c as a plane intersecting with the $X$ space. The intersection of the regression function and the $X$ space defines a separating hyperplane ($\alpha + \beta^T x = 0$) that separates the chosen segment into two sub-segments. The slope of the hyperplane is given by $\beta$ while its location is determined by $\alpha$. To satisfy the meaningfulness objective, we locate the hyperplane so that it passes through the center of the observations in the segment (Figure 3d). We accomplish this by dividing along $\alpha' + \beta^T x = 0$.

The primary difference between this approach and other binary tree methods (such as CHAID) is that the hyperplanes need not be perpendicular to the axes of the $X$-space. The use of a response measure ($\tilde{V}^{\pi_h}$) and the continuous nature of this response variable also distinguishes this approach from both clustering and classification methods. Clustering methods generally do not include a response variable. They focus on the representative objective without regard to the homogeneity criterion. Classification methods do use a response measure, but require that the response measure be binary or discrete.

4. **Dynamic Optimization**

Recall that the firm’s objective is to maximize its discounted aggregate profits. Having designed a discrete state space, two tasks are required to identify the optimal policy: (1) for each state we need to estimate the (one-period) rewards and transition probabilities for both the “Mail” and
“Not Mail” actions; and (2) using these estimated rewards and transition probabilities, we can use standard techniques to calculate the value function for a given policy and then iterate to improve upon that policy.

Figure 3: Dividing Segments

Estimating the Rewards and Transition Probabilities

In the original applications for which dynamic programming was first proposed, the rewards and transition probabilities were known. However, in this application, and indeed almost any social science application, these model parameters are not known, and instead must be estimated from historical data. The traditional approach to estimating the rewards and transition probabilities is to estimate an underlying response process as a continuous function of the state variables according to an assumed functional form. This *parametric* approach is used by Gönül and Shi (1998) who estimate the probability that a customer will purchase as the underlying response process. We propose a different approach for estimating the rewards and transition probabilities.
For each state and mailing decision, we simply observe from the historical data the average (one-period) reward and the proportion of times customers transitioned to each of the other states. We claim that this non-parametric approach offers four advantages.

First, the next state, after a transition, depends not only on whether a customer purchased, but also on how much they spent. Explicitly estimating a customer response function under the parametric approach therefore requires a model of purchase probabilities, together with a second jointly estimated model describing the size of the purchase (conditional on purchase). To derive the rewards and transition probabilities we would then need to integrate over the probabilities of the relevant outcomes, which depend on the definition of both the current state and each of the destination states. The process would be both extremely complex and sensitive to errors. It is unlikely that such a model would have practical relevance. Gönül and Shi (1998) abstract away from this problem in their model by both focusing on a very simple state space and only considering whether customers purchase (ignoring the variation in the size of those purchases).

Second, the functional form assumptions under the parametric approach can cause problems if the steady state probabilities change. We use an example with a 1-dimensional state space to illustrate this in Figure 4. Most of the historical observations are clustered in one portion of the state space (Area A). Because we can only estimate the response function using historical data, imposing a functional form favors accuracy in states with a lot of historical data (Area A) at the expense of states with little historical data (Area B). In Figure 4 we illustrate this trade-off by imposing a linear functional form. This may not be a problem if the steady state probabilities do not change under different policies. But if they do change, so that under the optimal policy customers transition to Area B, the errors introduced by the functional form assumption can be severe. One solution is to introduce additional degrees of freedom to the functional form, so that the response function is no longer linear. The non-parametric approach that we propose can be interpreted as an extreme interpretation of this suggestion. By estimating specific parameters for each state we allow for any and all non-linearities (and interactions) across states. Of course, the non-parametric estimates are less precise where there is less historical data, but the estimates are unhindered by the functional form restriction.
Third, the optimization portion of the dynamic programming algorithm favors actions for which (1) the errors in the expected rewards are positive and (2) errors in the transition probabilities favor transitions to more valuable states. This leads to upwards bias in the value function estimates (and can be interpreted as an application of Jensen’s inequality). We will later show that under the proposed non-parametric approach we can overcome this bias through cross-validation, as drawing a new sample of data yields an independent set of errors. In contrast, this solution is not available under the parametric approach. The distribution of the data across the states will tend to be stable across draws of the data, and so the functional form assumptions ensure that the errors are not independent (the errors illustrated in Figure 4 will occur in each sample).

Figure 4: Functional Form Assumptions

![Figure 4: Functional Form Assumptions](image_url)

Finally, under the proposed non-parametric approach, the precision of the transition probabilities is known. In particular, under weak assumptions the estimates of the transition probabilities follow a multinomial distribution. As a result, we can derive expressions for the bias and variance in the value function estimates (Mannor, Simester, Sun and Tsitsiklis 2004). Under the parametric approach it is not clear what distribution the estimates of the transition probabilities in
each state are drawn from. We could calculate the estimation errors for each state using the residuals, however, this is equivalent to reverting to the non-parametric approach.

As we acknowledged when earlier distinguishing our approach from the Gönül and Shi (1998) model, the parametric approach does offer an advantage. If the assumptions hold, it provides a means of predicting how customers will behave under mailing policies that do not arise in the historical data. We mentioned earlier the example of an historical policy that only mailed to customers who had recently purchased and observed that Gönül and Shi’s model provides a means of estimating how other customers would respond if mailed. The non-parametric approach is only feasible if there is stochasticity in the historical policy, so that there are historical examples of mailing to all customers. Of course the Gönül and Shi approach also benefits from stochasticity in the historical data. Indeed, absence of stochasticity will make the continuous parametric approach particularly sensitive to the errors illustrated in Figure 4.

Policy Evaluation and Improvement

With the rewards and transition probabilities in hand, the value function can be calculated using Bellman’s optimality equation (Bellman 1957):

\[
V(s) = \max_{\pi} \mathbb{E}_{r,T(s),s'} \left[ r_{r,s}(s) + \delta^{T(s)} V(s') | s, \pi(s) \right] \quad \forall s \in S
\]  

(2)

Here we use notations \( r_{r,a} \) as the random variable representing the immediate profit from the Markov chain after visiting state \( s \) and taking mailing action \( a \), \( \delta \) as the discount factor per unit time, and \( T \) as the length of the inter mailing time period after visiting state \( s \). Because we anticipate \( T \) would generally be included as one of the state variables used to define and construct the state space, we write \( T \) as \( T(s) \), recognizing that \( T \) is a random variable that is interdependent with \( s \).

For any fixed policy \( \pi \), the following equation characterizes the expected discounted aggregate profits (value function) when starting at state \( s \):

\[
V^\pi(s) = \mathbb{E}_{r,T,s'} \left[ r_{r,s}(s) + \delta^{T(s)} V^\pi(s') | s, \pi(s) \right] \quad \forall s \in S
\]  

(3)
If we use term $\bar{r}_{s,a}$ to represent the expected rewards earned from a customer in state $s$ when the firm chooses mailing action $a$, the above equation system (in general) can be expressed as:

$$V^\pi(s) = \bar{r}_{s,\pi(s)} + \mathbb{E}_{T,s'} \left[ \delta^T V^\pi(s') \left| s, \pi(s) \right. \right] \quad \forall s \in S$$

$$= \bar{r}_{s,\pi(s)} + \sum_{s'} V^\pi(s') \sum_T \delta^T p_{s,\pi(s) \rightarrow T,s'} \quad \forall s \in S$$

(4)

Here term $p_{s,\pi(s) \rightarrow T,s'}$ represents the joint probability that a customer in state $s$ after the mailing action $a$ will transition to state $s'$ and that the duration of the time period will be $T$. In the computation, we can directly estimate $p_{s,\pi(s) \rightarrow T,s'}$ from the data, which takes care of both the transition probability and the discounting. With a slight modification of notation we can express the above equation in vector form. Let $P^\pi$ denote a matrix for a given policy such that $P^\pi_{i,j} = p_{i,j,\pi(i)}$, let $\bar{r}^\pi$ denote the vector of expected rewards (with the $i$'th element equal to $\bar{r}_{i,\pi(i)}$), and let $v^\pi$ denote the vector with elements $V^\pi(i)$. Given this notation we have:

$$v^\pi = \bar{r}^\pi + P^\pi v^\pi,$$

which yields $v^\pi = \left( I - P^\pi \right)^{-1} \bar{r}^\pi$ as the value function under policy $\pi$.

Following the above notations, we can define a policy $\pi_H$ for the historical mailing decisions. We assume that the historical mailing actions out of each state $s$ follow the probability distribution observed in the data. The corresponding $P^{\pi_H}$ and $\bar{v}^{\pi_H}$ can be directly estimated from the data as well, which leads to the value function under this historical policy:

$$v^{\pi_H} = \left( I - P^{\pi_H} \right)^{-1} \bar{v}^{\pi_H}.$$  This provides both a benchmark against which to evaluate the optimal policy, and an obvious starting point for computing the optimal policy.

Having $v^{\pi_H}$, we use the classical policy iteration algorithm to compute the optimal mailing policy. The algorithm iterates between policy evaluation and policy improvement. In particular, the algorithm begins with a policy for which we calculate the value function. We then use this value function to improve the policy, which yields a new policy with which to begin the next iteration. The sequence of policies improves monotonically until the current policy is optimal. It is well known that the policy iteration algorithm converges to a stationary policy that is optimal
for the finite state infinite time horizon Markov Decision Process (Bertsekas 1995). In practice, the speed of convergence is surprisingly fast (Puterman 1994).

5. Implementation

We implemented the model on a dataset provided by the same women’s clothing catalog that provided the pilot study data. The items sold by this firm are in the moderate to high price range and almost all carry the company’s own brand name. We received data describing the purchasing and mailing history for approximately 1.73 million customers who had purchased at least one item of women’s apparel from the company. The purchase history data included each customer’s entire purchase history. The mailing history data was complete for the six-year period from 1996 through 2002 (the company did not maintain a record of the mailing history prior to 1996). In this six-year period, catalogs containing women’s clothing were mailed on 133 occasions, so that on average a mailing decision in this category occurred every 2-3 weeks. The company also mails catalogs for other product categories and the historical data received from the company contained a complete purchasing record for these other product categories.

State Variables

With the assistance of the firm we identified a set of 13 explanatory variables to describe each customer’s mailing and purchase histories. These variables can be grouped into three categories: purchase history, mailing history and seasonality. We begin with a discussion of the purchase history variables:

**Women’s Clothing Purchase History**

- **Purchase Recency**$_{it}$: Number of days since customer $i$’s most recent purchase prior to period $t$.
- **Purchase Frequency**$_{it}$: Number of orders placed by customer $i$ prior to period $t$.
- **Monetary Value**$_{it}$: Average size in dollars of orders placed by customer $i$ prior to period $t$.
- **Monetary Value Stock**$_{it}$: The discounted stock of prior purchases (see below).
- **Customer Age**$_{it}$: The number of days between period $t$ and customer $i$’s first purchase.
Purchase History For Other Categories

Purchase Frequency\(_{it}\) \(=\) Number of orders placed by customer \(i\) prior to period \(t\) for items outside the women’s clothing category.

The Monetary Value Stock\(_{it}\) measure can be distinguished from the Recency, Frequency, and Monetary Value measures by the increased weight that it gives to more recent transactions. In particular, the measure is calculated as follows: 
\[
p_{it} = \sum_{j \in J_{it}} \eta^{T_{it}} x_{ij}
\]
where \(J_{it}\) is the set of purchases by customer \(i\) prior to period \(t\), \(\eta \in [0,1]\) is a decay rate per unit of time, \(T_{it}\) denotes the number of units of time between period \(t\) and the \(j^{th}\) purchase, and \(x_{ij}\) describes the amount spent on the \(j^{th}\) purchase. In preliminary analysis we considered different values for these decay variables. This led to inclusion of two Monetary Value Stock\(_{it}\) variables with decay rates 0.9 and 0.8 per month respectively.

To describe the history of women’s clothing catalogs mailed to each customer we used two mailing stocks variables. These were defined analogously to the purchase stock measures:
\[
m_{it} = \sum_{k \in K_{it}} \eta^{T_{it}}
\]
where \(K_{it}\) identifies the set of catalogs mailed to customer \(i\) prior to period \(t\). The decay rates for these two mailing stock variables were set at 0.9 and 0.8 per week. These values were chosen because they yielded greater variance in the optimal mailing policies. The final estimates of the value function \(V\) were relatively stable to different values of these decay rates.

We also considered a variety of variables describing customers’ mailing and purchase histories from other product categories, but these variables had little effect on estimates of the optimal value function \((V)\) or the optimal mailing policies.

Analysis of the raw data confirmed the presence of seasonality in both the purchasing and mailing histories. To capture seasonality we used three variables.

- **Purchase Seasonality\(_{t}\)**: The average number of orders received in the corresponding week across all years in the dataset.
- **Mailing Seasonality\(_{t}\)**: The average number of catalogs mailed in the corresponding week across all years in the dataset.
Individual Seasonality\textsubscript{it} is the discounted sum of the number of purchases by customer \textit{i} in the same quarter in prior years.

To smooth the purchase and mailing seasonality variables we used a moving average for each measure. In the individual seasonality measure we gave greater weight to more recent purchases by decaying prior purchases using an exponential weighting function (using a decay rate of 0.9 per year). We also considered including dummy variables identifying the four quarters in a year. However, these had little impact on the findings. In general, while it is obviously important to include variables describing seasonality, the findings were robust to modifications in these variables (such as the use of different decay rates in the Individual Seasonality measure).

Finally, an additional variable was included to control for the variation in the length of each mailing period. This variable was labeled Period Length\textsubscript{t} and was defined as the number of weeks in the current mailing period (period \textit{t}).

**Design of the State Space**

Having defined the vector space \textbf{X}, we discretized it using the approach described in Section 4. This process is computationally intensive and so we focused on a random sample of 100,000 of the 1.73 million customers for this step. Data for the first 25 mailing periods (1996 through July 1997) were used to initialize the mailing and purchase stock measures, and the period from August 1997 through July 2002 was used as the estimation period. This estimation period comprised a total of 108 mailing periods.

To obtain initial estimates of the value function for the current policy (\( \tilde{V}^{\pi_H} \)) we randomly selected a mailing period in 1996 for each of the 100,000 customers and calculated the discounted profits earned from this customer in the subsequent periods. The randomization ensured that all values of the seasonality variables were represented. Using the total discounted profit as a dependent measure, we regressed \( \tilde{V}^{\pi_H} \) as a quadratic function of the \( (n) \) explanatory variables describing the customers’ mailing and purchase histories. To ensure that the estimates were robust, we repeated this process one hundred times and averaged the resulting parameter estimates to derive final estimates for \( \tilde{V}^{\pi_H} \).
The company supplements its purchase history data with additional information from other sources to make mailing decisions for inactive customers (defined as customers who have not purchased within the last three years). Because we do not have access to this additional data, this introduces the potential for bias in the calculated optimal value function (see later discussion). For this reason we only calculate the optimal mailing policy for customers who purchased in the three years prior to the current time period. Specifically, we divided the vector space $X$ into two half spaces $X'$ and $X''$, where observations in $X'$ represent customers who purchased within three years of the current time period. The state space discretization procedure was then conducted separately to design 500 states in each of the $X'$ and $X''$ spaces.

**Dynamic Optimization**

Having discretized the state space, we calculated the value function estimates for both the current and optimal policies. The policy improvement procedure was only conducted on states in $X'$. Before calculating the transition probabilities and expected rewards we first randomly selected a Validation Sample of 100,000 customers (none of these customers were in the sample used to design the state space). For comparison purposes we then separately estimated the transition probabilities and expected rewards for two different samples: (1) the 1.63 million customers that remained after removing the validation sample; and (2) a smaller sample of 100,000 customers randomly selected from this sample of 1.63 million customers.

As we discussed, the policy improvement algorithm focuses on the 500 states in which customers are active ($X'$). We need separate transition probabilities and expected rewards for each of the two possible decisions (“mail” and “not mail”), yielding 1,000 “state-action pairs”. Estimating the rewards simply requires calculating the mean reward for each of these state-action pairs. However, from each state there are potentially 1,000 possible transitions (including the other 499 active states, the 500 inactive states, and back to the same state). Therefore, the transition matrix has 1 million elements (1,000 potential transitions from 1,000 state-action pairs). Fortunately, most of the transitions are infeasible. For example, a customer who has placed three orders cannot transition to states for customers who have purchased fewer orders. Indeed, if customers do not purchase in a mailing period, they frequently transition back to the
same state. In Table 1 we summarize the amount of data available to estimate the expected rewards and transition probabilities under the 1.63 million and 100,000 customer samples.

Results

For ease of exposition we will refer to the improved policy as the “optimal” policy. However, we caution that the optimality of the policy is conditional on the design of the discrete state space and the accuracy of the transition probabilities and expected rewards. In Table 2, we report estimates of the current and optimal policy value functions for different discount rates. The discount rates are monthly interest rates, with a rate of 0.87% corresponding to an annual rate of 10%. The estimates for the current policy are derived using Sample 1. We restrict attention to active customers and weigh the estimates for each state by the number of visits to each state in the training sample. The table also reports the average percentage of (active) customers mailed a catalog in each mailing period.

*An observation is defined as an active customer in a single mailing period. The missing data reflects the acquisition of some customers after the first mailing period. “Zero transitions” describe elements of the transition matrix that were never observed in the data.

The value function for the current policy varies across interest rates. Although the policy does not vary, the rate at which future transactions are discounted affects the value function. The value function estimates for the optimal policy also vary with the interest rate. However, this
variance reflects both the change in the rate at which future transactions are discounted and
differences in the optimal policy. At lower interest rates it is optimal to mail a higher proportion
of customers because the model gives more weight to the favorable impact that mailing has on
future purchasing.

The value function estimates for the optimal policy in Table 2 are consistently higher in Sample
2, which is the smaller of the two samples. Because the transition probabilities and expected
rewards are calculated directly from the data, they inevitably contain error; the observed
transition probabilities and expected rewards are only estimates of the true transition
probabilities and expected rewards. The error in these estimates raises three important issues.

First, imprecision in the transition probabilities and expected rewards leads to variance in the
value function estimates. Second, because the expression used to evaluate the value
function, $v^\pi = (I - P^\pi)^{-1} \bar{F}^\pi$, is non-linear in the transition probabilities, errors in transition
probabilities lead to bias in the value function estimates. Third, in choosing actions to maximize
future discounted returns, the optimization algorithm favors actions for which the errors in the expected rewards are positive and errors in the transition probabilities favor transitions to more valuable states. This also leads to upwards bias in the value function estimates, and can be interpreted as an application of Jensen’s inequality (recall earlier discussion).

These issues have received little attention in the literature. Fortunately, the use of a non-parametric approach to estimate the transition probabilities and expected rewards yields a solution to all three issues. As we discussed, under weak assumptions the estimates of the transition probabilities follow a multinomial distribution. The properties of this distribution can be used to derive expressions for the bias and variance in the value function estimates (Mannor et al. 2004). The non-parametric estimation of the model parameters also ensures that when redrawing a new sample of data, the errors are independent. As a result we can test for the bias induced by the optimization by re-estimating the value function for the optimal policy using the Validation Sample.³ In Table 3 we summarize the corrected value function estimates and the standard errors of these estimates. Comparison of these findings with Table 2 highlights the impact that imprecision in the transition probabilities and expected rewards have on the value function estimates. After correcting the estimates, the value function estimates derived from the (larger) Sample 1 are now consistently higher than those derived from Sample 2.

In other findings of interest, we see that the benefits of adopting the optimal policy (compared to current policy) depend upon the monthly interest rate. At monthly interest rates higher than 10% the value function for the optimal policy is similar to that of the current policy. At these high interest rates the objective function is relatively myopic, giving little weight to transactions that occur in later periods. The findings indicate that the improvement on the current policy is relatively small in these conditions. This is perhaps unsurprising given the myopic focus of the current policy and the extensive feedback that the firm receives about the immediate response to its mailing policies. However, as the interest rate decreases, so that more value is attributed to future earnings, the difference in the estimated value functions increases.

³ In contrast, for the reasons described earlier (see Figure 4), the errors are not independent across samples when using the parametric approach to estimate the transition probabilities and expected rewards. Under that approach, cross-validation is not available, nor is there an obvious way to derive expressions for the bias and variance in the value function estimates.

**Comparison of Mailing Policies**

We can further illustrate the difference between the current and optimal policies by comparing how the mailing rates vary as a function of the explanatory variables. In Figure 5 we report the proportion of times a catalog was mailed in the historical data (the current policy), together with the proportion mailed under the optimal policy, for different values of the *Purchase Recency* and *Mailing Stock* variables. The optimal policy uses a 3% monthly interest rate and the figures only consider active customers. When customers become inactive (the recency measure exceeds 36 months) the optimal policy reverts to the current policy, which mails to approximately 14% of inactive customers.

Recall that *Purchase Recency* measures the number of months since the customers’ last purchase, while the *Mailing Stock* measure is a discounted sum of the number of catalogs mailed to customers in previous periods (using a decay rate of 0.9 per week). A mailing stock measure of 10 indicates a customer who has recently been inundated with catalogs, while a mailing stock of 1 indicates a customer who has received very few recent catalogs. The figures reveal several important differences between the optimal and current policies:
1. The current policy figure confirms that the firm does not consider a customers’ mailing history in its current policy. It keeps mailing to some customers even though they have
received a lot of recent catalogs, and does not mail to other customers even if they have not received any catalogs for a long time.

2. The optimal policy mails more often to customers who have not received many recent catalogs. Although the company judges that there is a low probability that the customers will respond immediately and hence does not mail to them (under the historical policy), the optimal policy judges that mailing to these customers increases the probability of future orders.

3. The optimal policy does not mail to customers who have received a lot of recent catalogs. After not mailing to these customers in one mailing period the mailing stock will drop (by approximately 2), so that many of them will receive a catalog in the next mailing period. The mailing rates are particularly low for customers who have purchased recently and received a lot of catalogs.

4. The small peak on the right hand side of the optimal policy figure indicates that the optimal policy mails to many customers who have not purchased for two years, particularly if these customers have not received many catalogs recently. This is consistent with customers purchasing in annual cycles. Interestingly, in the current policy figures, there is also a ridge indicating higher mailing rates if customers have not purchased for two years.

We caution that the values of the Mailing Stock variable reflect the mailing history under the current policy. As such, the figures answer the following question: how would the first mailing decision differ under the two policies? After implementing the optimal policy for several periods the shape of the figures would change because customers will have different values for the other variables. We also caution readers not to conclude that the optimal policy is stochastic. Observations that have the same value on one of the RFM variables generally have different values on other variables, so that the observations are distributed across multiple states. The policy within a state is deterministic, but when aggregating across states it appears stochastic.

It is also helpful to compare the findings in Figure 5 with the optimal policy described by Gönül and Shi (1998 at page 1258) in Figure 2a of their paper. The two policies are generally consistent, with both policies mailing with a high probability to customers who have not purchased recently and mailing less frequently to customers who have recently purchased. This comparison obviously requires a simplification as the differences in the state variables used in the two models prevent a direct comparison. For example, because the Gönül and Shi model does not include variables describing the mailing history, their policy does not vary with the number of recent catalogs that a customer received.
Comparison of mailing policies for customers who have placed a larger number of prior orders (not shown) is also interesting. The firm’s current policy is to mail often to these customers, while the optimal policy is to mail less often, particularly if the customer received a lot of recent catalogs. Gönül and Shi (1998) make a similar recommendation in Figure 2b of their model. One interpretation is that these customers are likely to respond even if they do not receive the current catalog, highlighting the risk of cannibalization (recall earlier discussion).

**Inactive Customers**

Intuitively the model learns from natural experiments in the data resulting from stochasticity in the historical mailing policy. An implicit assumption is that within each state the customers who are mailed are on average identical to the customers who are not mailed. It is helpful to illustrate the importance of this assumption using an example. Assume for the moment that there are two groups of customers. Mailing to a customer in the first group yields a profit of $100, while not mailing yields a profit of $0. For the second group, mailing yields a profit of -$10 and not mailing yields a profit of $0. If the firm can observe which group a customer is in it will mail to customers in the first group, but not mail to customers in the second group. Now assume that the model does not have access to the same information and so treats all customers as members of the same group. The model observes that $100 was earned when mailing to customers from this group and $0 when not mailing and so (incorrectly) recommends mailing to everyone in the group.

In preliminary analysis of the data the optimal mailing policy initially recommended mailing to almost all inactive customers. Discussions with the firm revealed that it uses additional information to decide which inactive customers to mail to. However, this information was not available when implementing the model. It is for this reason that we restrict attention to active customers. Observations for inactive customers remain in the model as the outcome for these customers affects the value function for active customers (many of whom eventually become inactive). When a customer becomes inactive, the model continues to implement the historical mailing policy and does not seek to improve upon this policy. This highlights the benefit of modularity; the optimization portion of the model is restricted to states in which there are sufficient data to evaluate the effectiveness of the alternative policies.
6. Field Test

While comparisons of internal validity are common in the management science literature, tests of external validity at the individual level are rare. In this section we describe validation of the proposed model in a large-scale randomized field test conducted with the company that provided the historical data. The field test was conducted over a period of six months and included twelve mailing dates and a total of 60,000 customers. These customers were randomly selected by the firm from its database of 1.73 million customers, subject to the restriction that the customers had purchased within 3 years of the starting date of the field test. This restriction is consistent with the focus on active customers in our application, and was designed to limit the number of inactive customers in the test.

Because the mailing strategies were only varied for six months, the predicted differences in the profits earned under the optimal and current policies are smaller than the differences presented in Table 3 (which evaluates permanent changes in the mailing policy). Moreover, the predicted improvements vary based on the initial states. In low value states the predicted profit improvements occur faster than in higher value states. For this reason, we broke the 60,000 customers into three approximately equally sized sub-samples based on values of the states in which customers started the test. We label the sub-samples as Low-Value, Moderate-Value and High-Value.4

The field test employed a 3x2 experimental design, reflecting the value of the states in which customers started the field test (the 3 sub-samples) and the mailing policies used during the test period (2 conditions). In particular, customers in each of the three sub-samples were randomly assigned to either a Treatment or a Control group. In the Treatment Group, mailing decisions for all 12 catalogs mailed during the 6-month test period used the proposed model, while the firm’s current mailing policy was used for the customers in the Control Group.

Following the company’s guidance, we adopted a 3% monthly interest rate when designing the mailing policy for the Treatment customers. Due to a time constraint, the estimated rewards and transition probabilities were estimated using Sample 2 (100,000 customers). Pre-processing of

---

4 We used (current policy) value function cutoffs of $24 and $71 to demarcate the three sub-samples. There were 20,030, 20,061 and 19,909 customers in the Low, Moderate and High-Value sub-samples (respectively).
the raw data for the larger 1.63 million sample is time-consuming because the data cannot all be held in computer memory. As a result, there was insufficient time to implement the larger sample before the field test’s first mailing decision. In this respect, the field-study can be considered a conservative test of the model’s potential.

Results

The results are summarized in Table 4, where we report both the profits earned during the 6-month test period and the value function estimates for the customers at the end of the period. We also report the sum of these two measures (which we label “Total Profit”). For each measure we report the actual and predicted differences between the Treatment and Control Groups.

The findings reflect the percentage difference between the Treatment and Control Groups, calculated as (Treatment-Control)/Control.

The findings for the Low and Moderate-Value customers are reassuring. The optimal policy transitioned customers to more valuable states by the end of the field test. For the Moderate-Value customers this was done without incurring any lost profits during the 6-month test period. For the Low-Value customers, transitioning customers to the more valuable states required

---

5 The value function estimates at the end of the Test Period were calculated using the firm’s current policy. Using the optimal policy instead of the current policy has little effect on the pattern of results.
increased mailing frequencies during the test period and these additional mailing costs outweighed the additional revenue earned during this period. Although the actual reduction in profits during the test period was larger than we had predicted (-96% versus -56%), the Total Profit improvements were roughly consistent with the predicted improvements (7% versus 11%).

Unfortunately the outcome of the field test for the High-Value customers was less favorable. For these customers the optimal policy mailed less frequently than the control policy and generated less revenue as a result, with the reduction in sales outweighing the savings in mailing costs. Although the findings for the High-Value customers were disappointing, a more detailed examination of the data reveals some promising evidence even for these customers. In Figure 6a we report the percentage difference between conditions in the average weekly gross profit earned from these customers during the field test. The gross profit measure includes revenue less the cost of goods sold (it does not include mailing costs). In Figure 6b we report the percentage of customers mailed on each of the 12 mailing periods in the Treatment and Control conditions.

Throughout the test the mailing rates in the Treatment condition were considerably lower than in the Control condition. Although there is an upward trend in the mailing rates under the Treatment condition, at the end of the test the number of catalogs mailed in the Treatment condition was still almost 20% smaller than in the Control. The gross profits are initially a lot lower in the Treatment condition, but by the end of the test period they meet or exceed the profits in the Control, despite the lower mailing rates. Indeed, in the last four weeks of the test, 20% fewer catalogs were mailed to customers in the Treatment condition yet the company earned over 2% more in gross profit (compared to the Control).

Further investigation revealed an explanation for the poor initial outcome with the High-Value customers. In the historical data the firm mailed over 85% of the time to the High-Value customers, so that only 15% of the data in these states was available to evaluate what would happen if the firm did not mail to these customers (it was as low as 7% in one state). Moreover, almost all of this “Not Mail” data occurred on just 9 of the 108 mailing dates in the historical data. It seems that there is simply insufficient data to reliably predict the impact of not mailing to the firm’s most valuable customers. In order to identify an optimal policy for its most
valuable customers, the firm would first need to introduce stochasticity in its mailing policy in order to better predict the outcome of not mailing to these customers.

Following the completion of the field test, the company revealed that on two occasions during the field test it mailed “Sale” catalogs containing a large proportion of discounted items. These mailing dates were in addition to the twelve mailing dates involved in the field test and had a large impact on demand (particularly the demand of the less valuable customers). Although these catalogs were mailed to an almost identical number of customers in the Treatment and Control samples, we did not control these mailing decisions, nor did we have any information about them. In particular, the optimal policy had access to less information than the firm’s policy, which we would expect to adversely impact its relative performance.
There are two approaches available for dealing with “Sale” catalogs. We could change the state space, so that it identifies whether the catalog mailed in the current mailing period is a “Sale” catalog or not. This would treat the type of catalog as an exogenous variable, but explicitly allow for changes in both the mailing policy and the model parameters (an analogous approach could be used to address other dynamic changes in the catalog content). Alternatively, we could treat the selection of whether to mail a “Sale” or regular catalog as a decision variable. In practice, this requires that there are always “Sale” and regular versions of the catalog available to be mailed. Because this is not always true in practice, this second alternative has less practical relevance.

We conclude that the optimal policy appeared to have been successful at increasing long-run profits for many of the customers involved in the test. In particular, mailing more frequently to less valuable customers increased predictions of the future value of these customers. However, the optimal policy initially did not perform as well as the current policy for the firm’s most valuable customers. Although the results for these customers looked more promising by the end of the test, overall the findings did not support the recommendation that the firm mail less frequently to these customers. Finally, the results of the field test highlight the importance of validating models of this type in the field. The limitations identified by the field test would not have been apparent had we restricted validation to analysis of the historical data.

7. Conclusions

We have presented a model that seeks to improve catalog-mailing decisions by explicitly considering the dynamic implications of those decisions. The proposed model is conceptually simple and straightforward to implement. Moreover, it is modular both in the components that firms choose to implement and the segments of customers that they implement it on. We have validated the model using both historical data and a large-scale field test. The findings show considerable promise, while also highlighting opportunities for further improvement.

A limitation of the proposed models is that it requires stochasticity in the historical policy. In particular, if the historical policy only mailed to customers who had recently purchased, then we cannot estimate the effects of mailing to customers who have not purchased recently. Fortunately, there is often considerable stochasticity in the historical policy due to both
randomized testing of mailing policies and changes in mailing policies over time. This is apparently true of catalog companies in general, not just the company from which we received data.

The level of stochasticity in the historical mailing policy varies across states. In the data that we analyze the firm almost always mailed to its most valuable customers, so that there is insufficient data available to evaluate what would happen if the firm did not mail to these customers. Fortunately the modularity of the model offers the firm the flexibility to only implement the model on customers for which there is sufficient stochasticity in the historical mailing policy. In particular, upon receiving the results of the field test, the firm was enthusiastic about implementing the proposed model with its less valuable customers but preferred to maintain its current policy with its more valuable customers.

There are at least two important issues that we have left for future research. First, when designing the state space we sought to group together customers with similar value function estimates. We did so using an initial estimate of the value function under the historical policy. It would be interesting to investigate the extent to which the design of the state space would change if we used final value function estimates under the optimal policy. Although this issue is not specific to our proposed model, the issue has not received much attention in the literature. Nor is it obvious how to address the problem as most of the potential solutions have difficulties. For example, the value function estimates for the optimal policy are the same for all of the customers in each state, and so re-designing the state space with these values will yield essentially the same states. The field test only provides 6 months worth of data, and so it is not possible to calculate the on-policy value function directly from this data. Even comparing the steady state probabilities under the current and optimal policies is a challenge. In the field test we can evaluate the distribution of customers’ final states. However, the field test focuses on a fixed sample of customers, while the dynamics in the overall system also reflect new customers arriving.

Second, we have not addressed the issue of how many states to use in the analysis. This issue introduces a trade-off. Classifying the observations more finely by using a larger number of states offers additional degrees of freedom with which to optimize. On the other hand, as we
have shown, the accuracy of the value function estimates depends upon the accuracy of the rewards and transition probabilities. Using a larger number of states results in fewer observations to estimate these model parameters. Validating the policies on a separate sample of validation data offers one option for resolving this trade-off. Because this issue is again not specific to the proposed model, we leave further investigation to future research.
